There has been growing concern during and since the 1990s about the effect that the toxicity and persistence of heavy metals will have on the biosphere. Consequently, these new environmental pressures have challenged analysts to find better experimental procedures for handling, recognition and evaluation of traces of heavy metals.

Moreover, the determination of low levels of heavy metals in seawater has received particular attention as a way of assessing the early impact of human activities on the marine environment. It is necessary to protect the marine and continental waters against contamination so as to allow suitable conditions for the maintenance of aquatic life and the various uses derived from aquatic life.

It is not the metal concentration alone that enables an environmental diagnosis to be made but the way metal combines with other elements to form species. These species are responsible for the biological behavior of the heavy metal under consideration, as its bioavailability will determine the amount of harm it may cause. Thus, ''speciation'' studies should be conducted to assess the potential environmental impact of human activities.

From the analytical point of view, seawater and brines may be considered to be closely related systems in terms of matrix effects and analytical difficulties. Hence these two systems will be included in this article although the aims of heavy metal detection and determination might be diverse in each case.

Analytical inaccuracies that arise from the high salt content of the seawater or brine solutions are exacerbated by the low levels of trace metals, which require careful control of contamination during sample collection and analysis and very sensitive analytical techniques.

Different techniques for the determination of trace metals in seawater, such as spectroscopic and electroanalytical methods, will be discussed here in terms of their performance in dealing with the problem of trace metal detection and determination.

Even the term ''trace'' has had different meanings over the years, normally being associated with the detection limit of the technique employed (''traces'', ''footprints'' or ''trails'' have a lot to do with the way they are observed). Amounts that would have been considered traces in the 1960s are probably no longer considered as such in the 1990s, as detection limits for most heavy metals have been lowered by three to six orders of magnitude (using ''state of the art'' techniques) since the late 1960s.

Special attention has been paid to the preconcentration of the analyte and its isolation from the matrix constituents which might obscure its accurate determination. A variety of separation–preconcentration methods will be presented, with a strong bias towards those procedures leading to some kind of automation, because pretreatment of the samples is often time-consuming and prone to contamination and may lead to an incomplete recovery of the analytes.

Flow injection analysis (FIA) has appeared as a solution to time-consuming and complicated separations and it will also be discussed in relation to alternative forms of analysis, especially in terms of its ability to perform speciation studies.

1 INTRODUCTION

Interest in the determination of heavy metals at trace levels in seawater derives from the importance that has been placed on the study of the fate of accumulative toxins in nature.

Marine chemistry, marine biology, geochemistry, and environmental science researchers are interested in the horizontal, vertical, and seasonal distribution of trace metals in seawater, as well as in trace metal biochemical and geochemical cycles in the ocean. Moreover, the determination of low levels of heavy metals in seawater has received particular attention as a way of assessing the early impact of human activities on

Encyclopedia of Analytical Chemistry

the marine environment, as a necessary preliminary to protecting marine and continental waters against contamination so as to allow suitable conditions for the maintenance of aquatic life and the various uses derived from it.

Most coastal nations have passed regulations in order to assess and control the contamination of their marine waters. To illustrate the importance that has been given to this issue, European Community Directives on the quality of continental and marine waters should be consulted: for marine ecosystems European Directive 79/923/CEE[1] limits the levels of Ag, As, Cd, Cr, Cu, Hg, Ni, Pb and Zn in seawater used to keep molluscs.

Knowledge of the metal concentration, together with the way it is combined with other elements to form species, enables an environmental diagnosis to be made. These species are responsible for the biological behavior of the heavy metal under consideration, as its bioavailability will determine the amount of harm it may cause. Thus, ''speciation'' studies should be conducted to assess the potential environmental impact of human activities.

From the analytical point of view, seawater and brines may be considered to be closely related systems in terms of matrix effects and analytical difficulties. Hence these two systems will be included in this article although the aims of heavy metal detection and determination might be diverse in each case.

Analytical inaccuracies that arise from the high salt content of the seawater or brine solutions are exacerbated by the low levels of trace metals, which require careful control of contamination during sample collection and analysis and very sensitive analytical techniques.

Different techniques for the determination of trace metals in seawater, such as spectroscopic and electroanalytical methods will be discussed here in terms of their performance in dealing with the problem of trace metal detection and determination.

High salinity and complex chemical composition of seawater and brines, together with a very low concentration level for the heavy metals, are the main obstacles to their proper analysis. Special attention has been paid to the preconcentration of the analyte and its isolation from the matrix constituents which might obscure its accurate determination. A variety of separation–preconcentration methods will be presented, with a strong bias towards those procedures leading to some kind of automation, because pretreatment of the samples is often time-consuming and prone to contamination and may lead to an incomplete recovery of the analytes.

FIA has appeared as a solution to time-consuming and complicated separations[2] and it will also be discussed in relation to alternative forms of analysis, especially in terms of its ability to perform speciation studies.

2 ANALYTICAL CHEMISTRY OF HEAVY METALS

2.1 Challenges Posed by the Ever-increasing Need to Improve Detection Limits

The identification and quantitation of heavy metals at trace levels has been widely studied and several books are available for consultation.[3–5]

Concern about the effects of the toxicity and persistence of heavy metals on the biosphere is growing. These new environmental concerns have challenged analysts to find better experimental procedures for handling, recognition and evaluation of traces of heavy metals.

What is meant by ''better experimental procedures''? This is a difficult question to answer, because it depends on the purpose of the trace determination, which might be classified by the following:

- precise concentration determination
- concentration profiles assessment
- bioavailability determination.

Precise concentration determination should be understood as a means of selecting those operations that pursue the highest accuracy and reproducibility for a single set of measurements. This case is the most frequently used in the development of new techniques, where interest is focused on finding novel ways of improving the features of merit of the technique.

Concentration profiles assessment here refers to operations that obtain information through analysis of a large number of sets of samples taken at different locations at different times. In this case, a new feature of merit, analysis frequency, which will reflect the quantity of reliable data obtained per unit time should be added.

Finally, bioavailability determination is one of the most recent requirements of the analytical chemist involving knowledge of the chemical form in which the analyte is present in the sample.

Here, the chemical ''species'' is the object of the analysis, and the features of merit will be referred to each species involved, because the toxicity of the heavy metals is related to the way that they could be introduced into living organisms (i.e. as the ''chemical species'').

Each of these alternatives may present the analyst with the need to use a different approach, from the evaluation of a large number of samples in a short period of time, to the accurate measurement of a single set of samples or the establishment of the chemical form in which the trace metal is encountered. Even the term ''trace'' has had different meanings over the years, normally being associated with the detection limit of the technique employed (''traces'', ''footprints'' or ''trails'' have a lot to do with the way they are observed). Amounts that would

have been considered traces in the 1960s are probably no longer considered as such in the 1990s, as detection limits for most heavy metals have been lowered by three to six orders of magnitude (using ''state of the art'' techniques) since the late 1960s.

In the early 1960s, the rise in the use of atomic absorption spectrometry (AAS) and the decline of atomic emission spectrometry (AES) produced a variety of studies using flames as ''atom cells'' to reveal the potential of this novel technique when compared with prevailing trace analysis techniques.

The average limit of detection (LOD) by that time was in the order of the parts per million for the refractory elements and around the parts per billion range for the easily atomized metals (Zn, Cd). It should be emphasized that the term ''LOD'' used then corresponded strictly to an instrumental LOD, while this concept was later changed to the expression ''methodological limit of detection'' (MLD). The MLD reflects more closely the environment of ''real'' samples than does the LOD, which reflects the instrument performance, usually expressed against a solvent blank and tending to enhance the value of the instrumental technique. (According to IUPAC (International Union of Pure and Applied Chemistry) definitions, LOD is the concentration that produces a signal equal to three times the standard deviation of the blank signal, after a number of determinations of that blank. This LOD is essentially instrumental and should not be confused with the MLD which is defined as the minimum concentration that can be reported as different from zero at a 99% confidence level. The sample containing the analyte whose MLD is being assesed should be compared to a blank that should be clearly defined and that has undergone the same analytical procedure as the sample.)

In the field of the electroanalytical techniques, stripping analysis over Hg (mainly anodic) appeared to be a promising technique for the easily reducible metals, even considering that anodic stripping voltammetry (ASV) is prone to interference when high ionic strength solutions (the case of seawater and brines) are used.

Later, spectroscopists developed a new atom cell, the electrothermal atomizer (ETA), which improved detection limits several times when background interferences were handled properly, while new electroanalytical procedures derived from stripping analysis become more popular as most of the inconveniences of the former ASV diminished or were eliminated.

The use of inductively coupled plasmas (ICPs) as atom cells introduced a new dimension to metal trace analysis, as detection limits were lowered by two or three orders according to the detection mode selected: inductively coupled plasma/optical emission spectrometry (ICP/OES) or inductively coupled plasma mass spectrometry (ICPMS).

The evolution of the detection limits for some heavy metals may be summarized as follows.

2.1.1 Spectroscopic Methods

In most cases, improvements in detection limits can be associated with the development of new instruments that enhance the signal-to-noise ratio via digital handling of the output signal or by coupling the atomic cell to newly developed detectors like mass spectrometers, or through the development of new on-line analytical procedures that improve the MLD. This becomes evident when observing the evolution of the detection limit for the same metal and technique over the years. FAES (flame atomic emission spectrometry) limits were enhanced when ICP excitation was available, although the excited species might not be the same. Flame atomic absorption spectrometry (FAAS) limits remained almost constant or, in other words, they did not follow the evolution of the electronics and data handling procedures as it would have been reasonable to predict, the explanation being that AAS signals are relative and do not depend so strongly on sensitivity and noise reduction procedures.

The real improvement in AAS MLDs was obtained when the flame atomic cell, continuously fed by spray chamber nebulizers, was replaced by discrete atomizers (mainly ETA) where the atomic cloud is confined giving rise to transient signals which are easily amplified and integrated.

Several important factors should be mentioned when discussing the enhanced sensitivity obtained over the years for electrothermal atomic absorption spectrometry (ETAAS):

1. The use of chemical modifiers: the introduction of a chemical reagent (called the modifier) in excess with respect to the solution to be measured by graphite furnace atomic absorption spectrometry (GFAAS), has proved efficient in converting the analyte element into a phase of higher volatility and/or in increasing the volatility of concomitants.[6,7]
2. Atomizer development has taken place through the introduction of new atomizing platforms as already mentioned,[13–15] new atomizer materials like W or Mo,[8,9] and new ways of heating as transverse heating.[10–12]
3. New background correction systems[13–15] have been used.

Finally some of the improvements found in ICP/OES could be ascribed to new sample introduction systems, together with enhanced data handling capabilities.

2.1.2 Electroanalytical Methods

Although acquisition of data for these methods is hindered by the different nomenclatures, it could be said that the enhancement in LODs produced over the years is a consequence of improved data acquisition and data treatment devices. However, it is important to point out that stripping techniques allow better MLDs because the electrolysis time can be managed.

2.2 Preconcentration and Speciation

2.2.1 Preconcentration

The nature of the matrix in which the trace metal is embedded might, however, also condition the analytical performance of the procedure developed. As mentioned earlier, what makes heavy metals analysis in seawater or brines so difficult is the low level in which heavy metals are usually found in these media and the highly saline matrix that contributes to a worsening of the detection performance.

Matrix elimination, sample pretreatment, or simply sample introduction, have been problematic issues in most heavy metals determination techniques, where accurate analyses are sought. No matter which instrumental device is used for the detection, saline samples will generally need special treatment before the analyte reaches the detection stage.

In any case, even if the lowest detection limits were achieved, some of the heavy metals present in seawater or brines cannot be quantified because their concentration levels in those matrices are below the LOD attainable, and some way of increasing their concentrations needs to be used in order to obtain a signal that is at least ten times greater than the standard deviation of ten replicates of the blank.

The set of operations performed with the aim of increasing the analyte concentration is usually referred to as ''preconcentration'', and it has become a discipline of interest among the analytical procedures for trace analysis. Again, available ''batch'' preconcentration methods have evolved from macro- or semimicroscale solvent extraction or ionic exchange to microscale ''on-line'' operations.

Preconcentration steps could be classified according to the phase equilibria involved:

1. solvent extraction
2. ion exchange
3. adsorption methods.

These procedures, or a combination of them, have been applied to seawater and brines. Some of the published studies are summarized in Table 1.

Usually, highly saline matrices require a conditioning step to eliminate or diminish the concentration of the salts that cause interference. This conditioning step might also act as a preconcentration step, and the detection device will dictate the extent of conditioning needed, as shown later.

As can be observed in Table 1, preconcentration is often performed using ion-exchange resins, including the so-called ''chelating'' resins in which the functional group complexes the analyte. These have been included in this group as the final process will be ionic exchange in both resin types. Chelating resins will behave more selectively than plain ionic exchange resins, as a covalent complex is formed between the metal atom and the donor atoms of the ligand (i.e. O, N, S); furthermore, these complexes will be less prone to the influence of ionic strength which seriously affects electrostatic interactions like those observed in ordinary ionic exchange resins. This allows the use of deionized water prepared standards even when measuring seawater samples.[46] Specially prepared fillings combining an inert support like silica with an organic ligand, like oxine derivatives, have also been employed, their selectivity and rigidity (they do not swell like the 100% organic polymers) being their main advantage. However, commercial chelating resins like Chelex 100 might be used with minor mechanical adjustments to compensate for the characteristic swelling. More recently strongly cross-linked resins like Muromac have been employed with good results in terms of selectivity and diminished swelling characteristics, but on-line operation with these resins might be severely impaired due to the low diffusion rate of the metal ions into the resin which in terms affects the chelating velocity.[47]

The choice between batch and on-line operation will depend on several practical considerations, with cost being one of the major issues to be taken into account. Most operations can be performed off-line and the samples can then be processed rapidly, making this approach competitive with on-line processing in terms of time employed, although the probability of contamination or analyte losses is still a serious drawback.

Commercial instruments can be fitted with automatic sampling devices capable of handling hundreds of vials in which samples, standards and blanks may be placed. Later, associated software will perform the necessary operations to calibrate and measure the analyte concentration in each sample.

This automation is particularly useful when multielemental detection systems (typically ICP/OES or ICPMS) that present such advantage over single-element on-line systems (typically HG/AAS, or GFAAS) are used.

Since it was first introduced by Ruzicka and Hansen in 1975[48] the FIA, which involves the introduction

Table 1 Preconcentration procedures

Element	Characteristics	Ref.
Solvent extraction		
Bioactive	Use of solid-phase extraction and high-resolution ICPMS	16
Cd	Preconcentration by solvent extraction	17
Fe, Cu	Use of 2-hydroxy-1-naphthaldehyde-4-phenyl-3-thiosemicarbazone extraction	18
Sn (tributyl)	Use of solvent extraction and HG/ETAAS	19
Yb	Coprecipitation and solvent extraction	20
Zn	Solvent extraction using a new chelating agent	21
Ion exchange		
Cd	Use of a dynamically coated column of quaternary ammonium salt on C_{18}-bonded silica gel	22
Cd, Cu, Pb	Chelating resin preconcentration and Hg(II)-assisted elution	23
Cd, Pb	Fully automatic on-line separation preconcentration system, using a Chelex 100 Microcolumn	24
Cu, Mo	Use of Muromac A-1 chelating resin	25
Cu, Ni, Cd	Synthesis, properties and applications of silica-immobilized 8-quinolinol	26
Pb	Use of a chelating resin	27
Pb	Use of Chelex-100 for isotope ratio determination	28
Rare earths	Use of poly (acrylaminophosphonic dithiocarbamate) chelating fiber	29
Several	Use of a cellulose–zinc hydroxide system	30
Several	Chelating resin preconcentration	31
Trace elements	Use of immobilized quinolin-8-ol silica gel	32
Trace elements	Ion chromatographic separation system: use of nitrilotriacetate chelating resin	33
Zn	Use of a dynamically coated column of methyltricaprylylammonium chloride on octadecylsilyl silica	34
Sorption/adsorption		
Ag	Coprecipitation mercury(II) sulfide	35
Cr(III)	Adsorption of silica	36
Cu, Mn, Ni	FI on-line sorption in a knotted reactor	37
Fe(III)	Sorption of the 3-(2-pyridyl)-5,6-bis (4-phenylsulfonic acid)-1,2,4-triazine complex with poly(chlorotrifluoroethylene) resin	38
Hg, Hg (methyl)	Sorbent extraction	39
Mo, V, Zr, Cr	Sorption preconcentration	40
Pb, Cu	On-line Co-APDC coprecipitation	41
Rare earths	Adsorption on activated carbon	42
Trace elements	Formation of water-soluble complexes and their adsorption on C_{18}-bonded silica gel	43
Trace elements	Use of cobalt diethyldithiocarbamate coprecipitation	44
Trace elements	Sorption ICP/OES	45

FI, flow injection; HG, hydride generation; APDC, ammonium pyrrolidine dithiocarbamate.

of a known volume of a liquid sample into a flowing unsegmented liquid carrier, where it is transported to a detector for measurement, has gone a long way in analytical chemistry towards becoming one of the ''established'' techniques of sample analysis and on-line sample treatment. FIA has gained acceptance as a powerful tool for rapid, accurate and economic performance of repetitive determinations. In this sense, and as will be shown later, most analytical procedures needed in the determination of heavy metals in seawater and brine require preconditioning and preconcentration steps which can be achieved using FIA.

FI operations may be performed with the aid of a very simple and economic device, the FI manifold, which consists typically of a propulsion unit (a peristaltic pump), a sample introduction device (a rotary injection valve), a reaction unit (a piece of tubing and/or complementary device), and a detector.

Continuous-flow processes like FI enjoy a flexibility that makes them suitable for performing most of the tasks associated with automation in the laboratory and obtaining the benefits of automation: an increase in the reliability (precision) of analytical operations; a reduction in the analysis time dedicated to routine operations; and a more efficient utilization of chemicals.

One of the major goals of FIA has been redefinition of the operational analytical scale on a micro basis, where volumes in the range of microliters are dealt with and consequently there are important savings in chemicals and waste is reduced to a minimum. Moreover, the miniaturization of FI systems has led to a sustantial reduction in the ''idle'' time between consecutive sample

plugs, speeding up on-line systems to make them compatible with detection devices that are very expensive when run idle (typically ICPMS or ICP/OES).

2.2.2 *Speciation*

Metal speciation could be broadly defined as the study of the ''distribution of the metals over distinct molecular binding forms'',[49] regardless of the effects on the biota that these molecular bindings might have, or it can be focused specifically on the impact on living organisms of these molecular forms. In either case there is a need to isolate the signals produced by those forms in order to establish the composition of the system. This isolation may be performed in situ on-line and continuously or before the detection step.

In natural systems the ''molecular form'' involved must be defined or characterized because natural molecules are too complex to be defined exactly. It is generally accepted that molecular size together with compound solubility are the most important parameters to be taken into account where the bioavailability of metals is concerned, and an operational or behavioral classification is often preferred to the plain chemical classification.

Del Castilho[49] clearly illustrates the operational definition through its application to dissolved and particulated matter in seawater, referring to the passage of the sample through a 0.45-μm pore filter to distinguish between dissolved (the fraction that goes through the filter) and particulate bound matter (the fraction deposited on the filter), leaving colloidal complexes in the soluble fraction.

Easily bioavailable metals will probably be found in the soluble fraction, while the insoluble fraction contains particles that will encounter a certain resistance to passing through cellular membranes. Furthermore, even the soluble fraction may need metal to dissociate from its binding particles before going through a successful diffusion process in order to enter the cell. Thus, molecular size determination will be needed on the insoluble fraction and some kind of dissociation behavior should be determined on the soluble fraction.

Bearing in mind both needs, speciation studies should lead to the determination of either the size of the substituents and/or the dissociation rate of the compounds likely to exist, together with characterization of the diffusion pattern of the heavy metals into the cellular membrane.

Several approaches have been used to achieve this purpose. These include previous separation of different molecular forms with the aid of on-line separative devices, like high-performance liquid chromatography (HPLC) and gas–liquid chromatography (GLC) in all their varieties, and operational characterization by means of differential pulse anodic stripping voltammetry (DPASV) and the time of contact concept. Redox speciation might be considered to be a special case of the soluble fraction speciation, provided the species belong to the soluble fraction. However, detailed knowledge of the distribution of oxidation states for a given metal may provide a useful probe of the redox conditions prevailing in the environment.

Some speciation studies performed on seawater are summarized in Table 2.

It must be emphasized that when ''total metal'' detectors are used (mainly spectroscopic) a previous separation stage is mandatory to achieve some kind of speciation. On the other hand, electroanalytical techniques, under special conditions, might perform speciation without previous separation, as most reduction

Table 2 Speciation studies

Element	Species	Separation/detection	Ref.
Cr	Cr(III), Cr(VI)	CCSV	50
Cr	Cr(III), Cr (total)	Seagoing method with detection by electron-capture gas chromatography	51
Cr	Cr(III)	Preconcentration by adsorption of silica, voltammetric detection	36
Cr	Cr(VI), Cr (total)	FI on-line separation and preconcentration with ETAAS detection	52
Cr	Cr(III), Cr (total)	Preconcentration in a flow-through electrochemical sorption cell and FAAS determination	53

potentials are modified according to the environmental conditions of the ionic species.

2.3 Interferences Most Commonly Encountered in Seawater and Brines

Tables 3 and 4 show the average composition for seawater with a salinity of 35 (inorganic constituents) and the most common organic compounds found for this seawater.

Taking into account the average seawater composition, one may predict that the most common interferences will be the chlorides and sulfates of the alkali and alkaline earth metals, and although it would not be evident at a glance, the organics that might form complexes with the heavy metals. However, these components will not always affect the measurements to the same extent, as interferences are closely related to the detection device employed.

Some facts about the chemistry of highly saline solutions must be remembered, particularly the tendency to form aggregates or compounds with the alkaline chlorides, or even the presence of the alkaline chloride, which may hinder the behavior of the trace metal, or physicochemical phenomena associated with high ionic strength solutions. Most natural or artificial brines will fall into the same category in terms of interference. Organic matter will affect the available heavy metal concentration, giving rise to the speciation studies. The interferences associated with each detection technique will be discussed later.

Sources of interference other than the matrix itself are the reactives that have to be used in the conditioning or preconcentration steps. This is particularly true for preconcentration systems in which the preconcentration factor is high and the reactives were used prior to this stage and are difficult to purify (i.e. conditioning with ethylenediamine tetraacetic acid (EDTA) or sodium salts). It is often necessary to pass the reagents through purification steps to ensure an appropriate level of impurities in the sample under consideration.

Table 3 Major composition of seawater[63]

Constituent	Seawater at $S = 35$
Na^+	10.77
Mg^{2+}	1.29
Ca^{2+}	0.4121
K^+	0.399
Sr^{2+}	0.0079
Cl^-	19.354
SO_4^{2-}	2.712
HCO_3^-	0.1424
Br^-	0.0673
F^-	0.0013
B	0.0045

S, salinity, is the weight in grams of the dissolved inorganic matter in 1 kg of seawater after all Br^- and I^- ions have been replaced by the equivalent quantity of Cl^-, and all HCO_3^- and CO_3^{2-} converted to oxide.

Table 4 Average concentrations of organics in seawater[63]

Components	Concentration in seawater ($\mu g\,C\,L^{-1}$)
Free amino acids	20
Combined amino acids	50 (to 100)
Free sugars	20
Fatty acids	10
Phenols	2
Sterols	0.2
Vitamins	0.006
Ketones	10
Aldehydes	5
Hydrocarbons	5
Urea	20
Uronic acids	18
Approximate total	340

3 SPECTROSCOPIC TECHNIQUES APPLIED TO SEAWATER ANALYSIS

3.1 Atomic Spectroscopies

Atomic spectra are unique in that, given the appropriate conditioning and instrumentation, the signals can be assigned univocally to a single element, making the spectroscopic techniques highly specific. Interelement interferences are seldom encountered provided the operation is conducted properly. This, together with the economy of operation, is responsible for the vast usage and popularity of atomic spectroscopies in their two main modes of operation, emission and absorption, and also, but to a lesser extent, fluorescence.

The use of flames as the traditional atomic source has receded with the introduction of novel ways of producing atomic vapors such as ETA, cold vapor generators, laser excitation probes or atmospheric pressure plasmas (ICP or direct current (DC) plasma) and so on, but although these new atom sources have many advantages, there are still thousands of flame-based spectrometers in operation.

3.1.1 Atomic Absorption Spectrometry

During the 1990s, ETA and to a lesser extent cold vapor generators, hydride generators and flames (in that order) have been used as atomic sources in atomic absorption studies on seawater and brines.

Table 5 FAAS

Element	Characteristics	Ref.
Cd, Co, Cu, Mn, Ni, Pb, Zn	On-line preconcentration and solvent extraction by FI system	64
Cr, Cu, Mn	Preconcentration on pretreated solid materials	65
Cu, Mo	Use of Muromac A-1 chelating resin with on-line preconcentration	25
Fe, Cu	2-hydroxy-1-naphthaldehyde-4-phenyl-3-thio semicarbazone extraction	18
Ni(II)	Preconcentration by flotation	66
Sn (organic)	Use of capillary column gas chromatography–AAS	67
Zn	Solvent extraction using a new chelating agent	21
Several	Preconcentration with modified silicas	68
Several	Karachi coastal waters	69
Several	Cobalt–diethyldithiocarbamate coprecipitation	44

Some of the latest studies using flame atomization are summarized in Table 5.

A quick look at Table 5 indicates that preconcentration procedures together with conditioning of the samples have been the objective of most FAAS studies related to heavy metal determination in seawater. No direct determinations are mentioned as a result of the poor LODs obtained.

The spectral interference caused by sodium chloride absorption bands is one of the most important drawbacks of ETAAS applied to seawater analysis. Background correction has proved useful but it still is not a solution to the problem for all the elements. Special devices such as Zeeman effect or Smith–Hiftje background correctors are needed when a deuterium lamp background corrector does not suffice, owing to the structured nature of the sodium chloride absorption spectra.[70–72] Moreover, vaporization of the analyte is also impaired by the massive amounts of salts present in the sample.

Table 6 shows similar compendia for ETA, mainly GF and related techniques.

Again, it can be seen that preconditioning of the sample has a major role in most of the studies presented, although several papers[9,74,75,81,90,92,94,99,103–105] are devoted to direct determination of the heavy metals, indicating that for some of them the actual LOD are good enough to render direct determination possible or that the metal concentration in those seawater samples is high enough to reach the existing LOD.

Several papers show the interest in coupling different automatic or semi-automatic sampling devices in order to speed up analysis and to enhance its reproducibility,[24,41,76,81,87,96,99,105,106,108,110] but the discrete nature of the atomization step has made achievement of this quite difficult.

Metals forming volatile compounds, such as hydrides, have been successfully analyzed by AAS or ETAAS. ETAAS is the most sensitive but, at the same time, the most difficult to couple with the HG step due to the discrete nature of both procedures, although hydride trapping has been used to overcome this difficulty. Several studies on this subject are shown in Table 7.

3.1.2 Inductively Coupled Plasma as an Atomic Cell, with Emission or Mass Spectrometry Detection

Since their commercial appearance in the 1970s, ICPs as atomic cells have continuously been improved in terms of performance and ease of operation. At the same time they have become available to more and more laboratories thanks to the decrease in their cost. As a result, ICP is now one of the most promising atomic cells in terms of its efficiency in producing and exciting atomic (or ionic) vapor, which may later be observed by its optical emission (ICP/OES) or by analyzing its mass spectrum (ICPMS).

Table 8 collects together several studies performed using ICP as an atomic cell and different detection devices.

Direct analysis of seawater samples poses a difficult task for ICP atom cells, because the elevated salt content interferes with the proper functioning of the sample introduction system. In this sense, a distinction between sample introduction in ICP/OES and ICPMS should be made. While optical detectors proceed at atmospheric pressure, mass spectrometers work under high vacuum and hence an interface should be provided for operation. Although solutions with a relatively high saline concentration (up to 1% solids) may be employed when using optical detection, in mass spectrometry (MS) instruments these solutions may produce deposition of material on the sampler and skimmer cones and subsequent restriction of the orifices, which in turn will cause a reduction in sensitivity and long-term stability.

Taking into account the nature of the final detection system (photomultiplier tube in ICP/OES and electron multiplier in ICPMS), it could be concluded that the latter would be more efficient than the former as no ''photon to electron'' transducer interface is needed. The increase in instrumental sensitivity may be over 1000 times for the electron multiplier when compared with the photomultiplier.

The extent and nature of interferences are also a function of the detection system: it was thought that the simplicity of the elemental mass spectra relative to the atomic emission spectra of the elements was an important advantage of ICPMS over ICP/OES. Although

not as important as in OES, numerous serious overlaps have been found in ICPMS. It must be emphasized that optical interferences are a result of the complexity of the atomic/ionic spectra, while mass/charge overlappings arise primarily from the generation of molecular species from sample, plasma, and matrix constituents. We cannot alter the atomic spectral complexity of a plasma constituent (we can use high resolution for solving some overlappings), but by changing plasma conditions and plasma chemistry, we can alter the nature of plasma constituents, controlling or eliminating certain spectral interferences in ICPMS.

Several specific sources of spectral interferences can be identified in ICPMS, including basic background species, isobaric or interelement spectral overlaps, analyte species spectral overlaps, and matrix-induced molecular species.

Table 7 HG/AAS

Element	Characteristics	Ref.

Se	Selenium species by FI HG in situ trapping	115
Sn	Separation by solvent extraction and HG/ETAAS	19

Interelement formation is one of the major drawbacks in MS detection: it is well known that matrix ions generated in the plasma deposit on the interface cones, changing the ionization potential of the plasma and reducing the transport efficiency of the analyte ions into the ion–lens region due to space charge effects. In each case signal suppression results.The combination of these ions with other matrix or plasma ions to form polyatomic interferences has also to be considered when the masses of those compounds lie close to the analyte mass.

This is the case for most heavy metals and the compounds formed between Cl, Br, O, Na, Ca, K, and H present in seawater and N or Ar ions present in the plasma, as can be seen in Table 9.

For these reasons, most of the procedures for seawater analysis begin with a pretreatment step that is used as a preconcentration and matrix-conditioning step at the same time. There are, however, a number of papers dealing with direct determination of heavy metals in seawater[125,137,142] by plain dilution of the samples, taking advantage of the very low LODs obtained with this technique and the relatively high contents of metals in the samples under consideration. It should be mentioned that in some direct determinations ETV was used for the same purpose: the reduction of salt content.

Isotopic dilution techniques, usually employed in radiochemical analysis, have been adapted to MS detection, giving rise to ICP/IDMS systems, that rely for their success on the existence of well-defined and carefully calibrated isotopic mixtures and the possibility of finding noninterferred lines for those analyte isotopes that do not appear in the sample.

3.1.3 Atomic Fluorescence Spectrometry

The major drawbacks of AFS for the analysis of heavy metals are the interferences, spectral or chemical, that can exist when analyzing a particular matrix. The former (spectral) are mainly caused by the atom cell design and the presence of molecular fluorescence of matrix concomitants and the latter (chemical) are associated with interactions between the analyte atoms and the matrix compounds either in condensed phase (loss of sensitivity caused by poor atomization) or in vapor phase, where quenching effects are very strong.

Then, obtaining a good LOD means that the concentration of the fluorescence quenching species in the vapor phase is eliminated or diminished and the interelement compounds that might be formed in the atomization step are broken down.

Flames and ICPs provide enough energy to atomize even the refractory elements, but at the same time the population of quenching compounds in those atom cells is high enough to eliminate the fluorescence signal. ETAs, on the other hand, will be free from fluorescence quenching species because no combustion gases will be present, but matrix gases within the furnace atmosphere will present a serious quenching problem.

From the point of view of the spectral source, it should be considered that because fluorescence signals are directly proportional to the spectral line source light intensity, conventional excitation sources like hollow cathode lamps, high-intensity hollow cathode lamps or electrodeless discharge lamps will produce poor excitation and consequently poor LODs while posing geometric limitations to the instrument developer. Lately, laser excitation has been the choice for obtaining the best LOD.

Heavy metal analysis by atomic fluorescence has been confined to a few cases in which the atomization conditions allow good sensitivity. These are described in Table 10.

As can be seen from Table 10, most of the studies performed on seawater by AFS employ a preliminary vaporization step: cold vaporization (Hg), HG (As, Se) or ETV (Ag) in order to ''clean'' the atomic vapor of interfering compounds and to facilitate the atomization step, avoiding the use of flames. Laser excitation is used when possible.

3.2 Other Atomic Spectrometries

3.2.1 X-ray Fluorescence Spectrometry

Few studies have been reported on heavy metal analysis on seawater or brine by X-ray fluorescence spectrometry (XRFS). The reasons for this could be found in the poor sensitivity of this technique and/or the need for cumbersome preconcentration and pretreatment steps. However, some laboratories have succeeded in certification experiments on seawater samples. Table 11 shows the reports found since 1989.

3.2.2 Nuclear Spectrometries

Neutron activation analysis has also scarcely been used for heavy metals determination in seawater or brine. The need for a neutron source or adequate facilities for

handling radioisotopes might be some of the reasons for the lack of applications of this technique in the field of seawater analysis. Some published papers are presented in Table 12.

Sample conditioning and preconcentration steps are dominant in the studies presented, while LODs are similar to those obtained with other techniques, meaning that little is gained by the use of nuclear techniques, except for those laboratories that already have facilities for such procedures.

4 ELECTROANALYTICAL TECHNIQUES

Electroanalytical procedures have been used for the analysis of heavy metals since the development of conventional (DC) polarography, and they have proved to be reliable methods for water analysis. The ever-increasing need to improve the LOD, as has been stated earlier, has been the driving force in the development of new electroanalytical technologies to improve the sensitivity and selectivity of the detecting devices and new ways to enhance the electroactivity of the sample species.

Technological improvements, focused mainly on the field of sampling and measuring current intensities and potential differences, have changed traditional electrolysis over a mercury drop to more sophisticated ways of observing the same or related phenomena. In this field, the major role played by computer-assisted techniques, under continuous development, that have set new milestones in electrochemical LODs should be stressed.

Voltammetry, based on the current–potential relationship in an electrochemical cell, and particularly with the current–time response of an electrode at a controlled potential, uses the current intensity at that potential as a means of measuring the concentration of the electroactive species.

Considering that the measured current is related to the rate of charge transfer through the electrode–solution interface, and that from an analytical point of view only Faradaic processes contribute to the overall sensitivity of the technique, then all the mechanisms which might enhance either the charge transference or the Faradaic to capacitive current ratio will be welcome. In the same direction, current sampling procedures will provide another means of increasing the sensitivity of the technique. It should be mentioned here that one of the major drawbacks of the electroanalytical techniques is the need to eliminate oxygen from the solutions in order to avoid its interference either as an electroactive substance

or as a competitor for the reduction of the metals at the electrode surface.

Stripping voltammetry, one of the electroanalytical techniques designed to deal with traces of metals, relies on the preconcentration of traces by their electrodeposition over a convenient electrode material (usually mercury) and then the release of the electrodeposited material, with the aid of a potential sweep, while measuring the curve i against V.

As the LOD will be a function of the ability to detect the difference between the current obtained with the analyte and the residual current (or blank current), then better results could be expected when reducing the residual current and increasing the sensitivity of the detecting device. Careful selection of the supporting electrolyte is mandatory in order not to add impurities or simply to contaminate the sample, giving rise to a signal superimposed on the analyte's signal, particularly when measuring current intensities in the nanoampere order.

Voltammetric analysis has been used scarcely in the determination of heavy metals in seawater or brine solutions. The reasons for this can be found in the widespread use of stripping techniques, which are more sensitive than classical voltammetric analysis.

4.1 Stripping Techniques

According to the nature of the species accumulated on the surface of the electrode material and consequently the nature of the potential sweep, different techniques may be described:

Table 13 Electroanalytical techniques

V, voltammetry; TTHA, triethylene tetranitrile hexa acetic acid.

1. ASV: the ''naked'' metals are reduced at the surface of the electrode (and hence accumulated) and then they are reoxidized by a potential sweep and the resulting current is measured.
2. CSV: the metals are complexed with proper ligands and adsorbed on to the electrode surface at a prefixed potential; the complexed metals are then reduced by a potential sweep and the reduction current is measured. This procedure is also known as adsorptive stripping voltammetry'' (AdSV). The addition of oxidant species may lead to a reoxidation of the complexes during the lifetime of the cycle, giving rise to catalytic adsorptive (cathodic) stripping voltammetry (CAdSV).

It can be said that the principal variables affecting the performance of a voltammetric technique are the electrolysis time, the stirring rate, the electrode area to volume ratio and the mode of the voltage sweep.[167] While the first three account for an improvement in mass transport to the electrode, the last takes into consideration the way the metal ions can be oxidized out of the electrode surface. Novel electrode surface materials, shapes and movements are then added to the previous classification, broadening the panorama of electroanalytical techniques available.

One of the latest developments in the field of the stripping procedures has been potentiometric stripping analysis or potentiometric stripping voltammetry (PSA or PSV): in this case, the system is treated as in ASV until the deposition has been completed; it is then disconnected from the potentiostat and the curve V versus i is measured.

Highly saline solutions may be analyzed directly by ASV or CSV provided that the electrolysis time is long enough to accumulate a quantity of analyte great enough to be measured accurately afterwards.

Each of the techniques briefly described above has different capabilities for seawater or brine analysis associated with them. Its high sensitivity, speciation ability, and the use of the matrix (NaCl) as support electrolyte are advantages, while the need for sophisticated equipment or mercury as electrode material (in recession nowadays) is a disadvantage.

Table 13 shows some of the latest studies performed on seawater and brine using electroanalytical procedures.

5 COMPARISON OF DIFFERENT APPROACHES

So far we have tried to give a broad panorama of the possible alternatives for the determination of heavy metals in seawater and in brine. Most of the analytical techniques available have been discussed, and a comparison of these alternatives is imperative in order to establish some useful guidelines at the time of choosing the appropriate technique of analysis.

The aims of heavy metal determination are of paramount importance in analyzing alternative procedures. At the beginning of this chapter (section 2.1) we classified the reasons for heavy metal determination into three broad categories, and the procedures for these determinations should be selected in consequence.

Modern analytical chemistry tends to keep the analyte in a ''clean environment'' reducing handling to a minimum, giving rise to the new breed of hyphenated techniques – those that include a separation step before the detection step. FI techniques have already been used for the determination of most heavy metals in seawater and brine, being employed not only with some of the previously described detection devices, but also with traditional detection systems like fluorescemetric and spectrophotometric devices.

Table 14 shows some of the latest studies on seawater and brine in which FI techniques have played an important role. This list is by no means exhaustive, as many FI studies have been mentioned before and will not appear in this table; furthermore, with one exception it only covers the 1990s.

The fact that UV/VIS[211–216] and chemiluminiscence[199–205] detection devices are used for the analysis of seawater samples (see Table 14) demonstrates that FI techniques are suitable for concentrating heavy metals to such a level as to allow the use of less sensitive detectors, without contamination by handling, and in some cases performing reagent purification in the same system.

Selecting the analytical procedure will be then a very demanding task, especially when starting from scratch, that is when one has to decide which equipment to purchase and which determination method to use. The reader is referred to the first paragraphs of this article in order to determine her or his needs.

There is a long-standing competition between analytical spectroscopists and analytical electrochemists about the efficacy of each technique for dealing with traces of metals. We will not enter in this discussion, but most of the literature consulted is devoted to spectroscopies (83%) and thus, unavoidably, there will be some bias towards spectroscopic methods for trace analysis.

With regard to the metal involved, and taking into account the usual concentration level in which the metal is found in seawater or brine, two broad metal groups could be mentioned: those forming some kind of volatile compounds, and the rest.

- ***Forming volatile compounds***: As, Se, Te, Pb, Sn, Sb, Ge, Cd and Hg belong to this category. They

UV/VIS, ultraviolet/visible.

may all form some kind of volatile compound, mainly their hydrides (except for Hg, which is volatile as the element). Volatile compounds will be decomposed at high temperatures to yield an atomic cloud, which in turn will yield adequate conditions for atomic spectroscopic methods, free from matrix interferences. For these reasons, HG or cold vapor generation are preferred when analyzing this set of metals, leaving electrochemical methods as a second choice.

- ***Metals that remain in solution (the rest)***: for those metals that do not form volatile compounds easily, a similar criterion for choosing the appropriate technique could be used. Those that will be easily volatilized (not as compounds but as elements) should be analyzed by spectroscopic techniques, as sensitivity will be high if they are easily volatilized. Nevertheless, electrochemical techniques may be preferred for some easily reducible ions or ions which form easily reducible complexes (Co, Cr, Cu, Fe, Pb, Zn).

A new concept has been added to the usual features of merit in analytical procedures: the number of determinations that can be performed per unit time. This is a measure of the capabilities of the technique to deal with a heavy workload, and is used to evaluate its automation potential. Taking into account that most of the sample preparation work might be performed using FI techniques, detection will be the determining step. In this field, multielemental detection devices, such as those that are usually coupled with ICP atom cells, are one of the major improvements in terms of efficiency and operation economy.

Almost all detection devices show instant response to the analyte except for stripping techniques, which require a certain electrodeposition time before reaching the measuring step. Thus, stripping methods may have a poor performance in terms of analysis throughput.

In summary, all techniques presented here will yield the best results when used by trained professionals who have mastered the analytical procedures, and hence the choice of technique will be dictated by common sense rather than for technological reasons.

ACKNOWLEDGMENTS

The author wishes especially to thank Dra Mabel Tudino for her wise advice and her collaboration on the manuscript, and to the people of Laboratorio de Análisis de Trazas who have made this work possible.

The hydride generation (HG) technique using sodium tetrahydroborate(III) (SBH) is applied to atomic absorption spectrometry (AAS), inductively coupled plasma atomic emission spectrometry (ICP/AES), and inductively coupled plasma mass spectrometry (ICP/MS). All the detection limits using the HG technique are less than those for solution nebulization. Chemical speciation in the HG technique is effected by changing the pH of the solution, the cold trap method and various hyphenated techniques. The author used a gas–liquid separator containing a spiral tube to separate efficiently the hydrides from solution. This minimized the consumption of the sample and SBH solutions and of the hydrogen evolution compared with the continuous-flow method. The author used a high-resolution ICP/MS instrument which allowed the use of hydrochloric acid in the sample preparation of arsenic and the determination of selenium without its isotopes.

1 HISTORICAL REVIEW OF HYDRIDE GENERATION SPECTROSCOPIC ANALYSIS

Since AAS was founded by Walsh,[1] most metals have been determined rapidly with high sensitivity. However, the sensitivity of metalloid elements such as arsenic (CAS 7440-38-2) and selenium (7782-49-2) were low in AAS, because these elements are difficult to atomize directly. In 1969, Holak[2] generated arsine (7784-42-1) by reaction of zinc (7440-66-6) with hydrochloric acid (10035-10-6) and collected it in a U-tube in liquid nitrogen (7727-37-9). The hydride was then warmed and passed into a flame in an atomic absorption spectrometer. In his method, arsine was separated from solution containing several interferents and determined with high sensitivity. As shown in Equations (1–4) arsenate (15584-04-0) is reduced to arsenite (15502-74-6) and then reduced to arsine, which is decomposed to arsenic (7440-38-2) in the flame.

$$Zn + 2HCl \longrightarrow ZnCl_2 + 2H \quad (1)$$

$$H_3AsO_4 + 2H \longrightarrow H_3AsO_3 + 3H_2O \quad (2)$$

$$H_3AsO_3 + 6H \longrightarrow AsH_3 + 3H_2O \quad (3)$$

$$AsH_3 \longrightarrow As + 3H \quad (4)$$

Schmidt and Royer[3] reduced the metalloids with SBH (16940-66-2) instead of zinc. By using SBH with acid the reduction yield is increased, the time required is shortened and the reagent blank is lowered. The reaction schemes for arsenic and selenium are shown in Equations (5) and (6). Arsenate is reduced to arsenite and then reduced to arsine, which is decomposed to arsenic thermally.

$$4H_3AsO_4 + BH_4^- + H^+ \longrightarrow 4H_3AsO_3 + H_3BO_3 + H_2O \quad (5)$$

$$4H_3AsO_3 + 3BH_4^- + 3H^+ \longrightarrow 4AsH_3 + 3H_3BO_3 + 3H_2O \quad (6)$$

Selenite (14124-67-5) is reduced to hydrogen selenide (7783-07-5), which is decomposed to selenium, as shown in Equations (7) and (8).

$$4H_3SeO_3 + 3BH_4^- + 3H^+ \longrightarrow 4H_2Se + 3H_3BO_3 + 3H_2O \quad (7)$$

$$H_2Se \longrightarrow Se + 2H \quad (8)$$

Elements that form gaseous hydrides (12184-88-2) at ambient temperature are called generically hydride-forming elements. Table 1 summarizes the properties of hydride-forming elements.[4]

Table 1 Properties of hydride-forming elements

Analyte	Hydride		Melting point (°C)	Boiling point (°C)	Solubility in water ($\mu g\,mL^{-1}$)
	Formula	Name			
As	AsH_3 (7784-42-1)	Arsine	−116.3	−62.4	696
Bi	BiH_3 (18288-22-7)	Bismuthine	−67	16.8	–
Ge	GeH_4 (7782-65-2)	Germane	−164.8	−88.1	Insoluble
Pb	PbH_4 (15875-18-0)	Plumbane	−135	−13	–
Sb	SbH_3 (7803-52-3)	Stibine	−88	−18.4	4100
Se	H_2Se (7783-07-5)	Hydrogen selenide	−65.7	−41.3	37 700–68 000
Sn	SnH_4 (2406-52-2)	Stannane	−146	−52.5	–
Te	H_2Te (7783-09-7)	Hydrogen telluride	−51	−4	Very soluble

ICP/AES was established between 1964 and 1965 by Greenfield et al.[5] and Wendt and Fassel.[6] Thompson et al.[7] first applied the HG technique to ICP/AES and determined simultaneously arsenic, antimony (7440-36-0), bismuth (7440-69-9), selenium and tellurium (13494-80-9). Houk et al.[8] combined the inductively coupled plasma (ICP) with mass spectrometry (MS) and constructed an ICP mass spectrometer. Powell et al.[9] determined arsenic, selenium, antimony, bismuth, tellurium and mercury (7439-97-6) by ICP/MS using a commercial HG system. There are several review articles on HG spectroscopic analysis. Nakahara reviewed HG/AAS[10] and HG/ICP/AES,[11] and Campbell reviewed HG/AAS and HG/ICP/AES.[12]

2 HYDRIDE GENERATION FOR SPECTROSCOPIC ANALYSIS

2.1 Hydride Generation for Atomic Absorption Spectrometry

2.1.1 Apparatus for Hydride Generation Atomic Absorption Spectrometry

There are several methods to separate the hydrides and to sweep them into a quartz cell in an atomic absorption spectrometer. These include the cold trap method, the batch method and the continuous-flow method. In the cold trap method, the hydrides are trapped in a U-tube in liquid nitrogen and then released thermally into a heated cell in an atomic absorption spectrometer.[2] The cold trap method is used for chemical speciation of the hydride-forming elements, since the sensitivity can be enhanced by enrichment of the hydrides in the cell. In the batch method, the hydrides are purged with carrier gas to the spectrometer as shown in Figure 1.[13] In the continuous-flow method, the hydrides are separated from solution and swept continuously into the cell. Since the former procedure is tedious, the latter method is used for the total determination.

Figure 1 Schematic diagram of the batch method. (Reprinted from B. Welz, M. Melcher, *Anal. Chim. Acta*, **131**, 17–25 (1981). Copyright 1981, with permission from Elsevier Science.[13])

Figure 2 Schematic diagram of the gas–liquid separator. Dimensions in inches. (Reproduced from P.N. Vijan, G.R. Wood, *At. Abs. Newsl.*, **13**(2), 33–37 (1974) by permission of The Perkin-Elmer Corporation.[14])

Figure 3 Schematic diagram of the fused-silica furnace. (Reproduced from K.C. Thompson, D. R. Thomerson, *Analyst*, **99**, 595–601 (1974) by permission of The Royal Society of Chemistry.[15])

Figures 2 and 3 show typical dimensions of a gas–liquid separator[14] and a quartz cell,[15] respectively. The sample and SBH solutions are separately conveyed with each peristaltic pump and mixed with a mixing coil. Tygon R-3603 (Norton) tubings are the best for the conveyance of gases and liquids. The hydrides formed are separated from solution in the separator and then swept into the cell. Usually nitrogen or argon is used as the carrier gas. The separator and tubes should be replaced with new ones after several uses, since some hydrides such as hydrogen selenide and plumbane are unstable and deteriorate with contaminants. The cell is heated electrically or with a combustible gas. The electric heating controls the cell temperature. The inner wall of the cell should be cleaned with sandpaper or mineral acids after several uses.

A graphite furnace in which the hydrides are trapped and atomized in situ has also become popular.[16]

2.1.2 Detection Limits and Ranges

Table 2 shows the detection limits of the hydride-forming elements using AAS, ICP/AES and ICP/MS.[17] The detection limits with HG are lower than those obtained by solution nebulization in each type of spectrometry and the limits in AAS lie at the parts per billion level. Since the ranges in AAS are regulated by the Lambert–Beer law, the ranges are narrow. Therefore, sample solutions must be concentrated or diluted depending upon the concentration.

2.1.3 Interferences

The HG process is retarded with transition metals such as copper (7440-50-8) and nickel (7440-02-0)[18] and the other coexisting hydride-forming elements.[13] The transition metals are eliminated with Chelex 100 chelating resin for the determination of arsenic, selenium and antimony.[19] Various masking agents are added to complex the transition metals, as shown in Table 3.

2.1.4 Environmental Sample Preparation for Hydride Generation Atomic Absorption Spectrometry

When the total amount of hydride-forming elements is to be determined, the sample should be decomposed. River waters are concentrated with nitric acid (7697-32-2) and sulfuric acid (7664-93-9) including boiling tips. Organic materials are digested with nitric, sulfuric and perchloric acid (7601-90-3). Siliceous residues deposited during the digestion are dissolved with hydrofluoric acid (7664-39-3).[19] Since selenium and antimony are oxidized during the digestion, selenate is reduced to hydride, forming selenite, by boiling with concentrated hydrochloric acid before hydridization (Equation 9).

$$SeO_3^{2-} + 2HCl \longrightarrow SeO_3^{2-} + Cl_2 + H_2O \quad (9)$$

Antimonate (20175-28-4) is reduced to antimonite with potassium iodide (7681-11-0) solution (Equation 10).

$$SbO_4^{3-} + 3I^- + 2H^+ \longrightarrow SbO_3^{3-} + I_3^- + H_2O \quad (10)$$

Table 2 Detection limits (ng mL^{-1}) for the hydride-forming elements

[a] FAAS, Flame atomic absorption spectrometry. (Revised by permission of JAI Press from T. Nakahara, *Advances in Atomic Spectroscopy*, JAI Press, Stanford, CT, 156 ,Vol. 2, 1995.)

Table 3 Masking agents in HG/AAS

Element	Masking agent	Interfering element	Ref.
As	1,10-Phenanthroline (66-71-7)	Cu(II), Ni(II), Pt(IV), Pd(II)	20
As	Thiosemicarbazide (79-16-6)	Cu(II), Ni(II), Pt(IV), Pd(II)	20
As	Thiourea (62-56-6)	Co(II), Cu(II), Ni(II)	21
As	Cysteine (52-90-4)	Co(II), Ni(II)	22
Sb	Potassium iodide (7681-11-0)	Ag(I), Cr(III), Cu(II), Sn(II)	23
Ge	Cysteine	Co(II), Ni(II), Cu(II)	24

Lead(II) (14280-50-3) should be oxidized to hydride forming lead(IV) (15158-12-0) with potassium peroxodisulfate (7727-21-1) or potassium dichromate (7778-50-9) just before hydridization.

SBH powder should be weighed out as quickly as possible and away from heat sources, since it is hygroscopic and inflammable. SBH solutions must be stabilized with small amounts of sodium hydroxide (1310-73-2) or potassium hydroxide (1310-58-3) and filtered with a filter paper before use.[25] The most commonly used acid in HG is hydrochloric acid, but sulfuric acid is used for the determination of antimony and tin (7440-31-5).

2.1.5 Chemical Speciation by Hydride Generation Atomic Absorption Spectrometry

HG depends upon the oxidation state of the hydride-forming elements and the acidity of a solution containing the elements. Inorganic nonhydride-forming species are determined differentially by subtracting the concentration of the relevant hydride-forming species from the total concentration. Agett and Aspell[26] determined arsenic(III) by HG, maintaining the pH between 4 and 5, and total arsenic by evolution from 5 M hydrochloric acid by AAS. Yamamoto et al. determined antimony(III) at pH 2 and total antimony with 1 M hydrochloric acid.[27]

Organic hydride-forming species are difficult to determine by controlling the acidity. As for arsenic, arsenite forms arsine, methylarsonate forms monomethylarsine $[(CH_3)AsH_3]$, dimethylarsinate forms dimethylarsine $[(CH_3)_2AsH_2]$ and phenylarsonate forms phenylarsine $[(C_6H_5)AsH_2]$. Hydrides trapped in the U-tube are released sequentially on standing at ambient temperature and atomized with an oxyhydrogen flame. The cold trapping methods used for chemical speciation are summarized in Table 4.

Chromatographic methods are the most reliable techniques for the separation of chemical species and are coupled to spectroscopic analyses to enhance the sensitivity, but this article is restricted to methods using HG. The cold trapping method is coupled with gas chromatography (GC) to refine its resolution. Andreae[34] speciated arsenite, arsenate, monomethylarsonate and dimethylarsinate by cold trapping GC/AAS after hydridization. HG/GC/AAS is exclusively used for the speciation of organotin compounds.[35] Since organotin chlorides are liable to adsorb on the packing materials in GC columns, the chlorides are hydridized with SBH before injection. Effluents from the GC columns are ignited with an oxyhydrogen flame to atomize tin in the effluents. Peaks obtained with capillary columns are better resolved than those obtained with packed columns, but the injection volumes with capillary columns are limited. Samples to be speciated by GC are extracted with organic solvents such as hexane (110-54-3) and purified by cleanup. GC cannot be used to speciate thermally unstable hydrides and nonvolatile species.

Table 4 Chemical speciation by the cold trapping method in AAS

Element	Chemical species	Ref.
As	As(III), As(V), monomethylarsine (593-52-2), dimethylarsine (593-57-7), monoethylarsine (593-59-9)	28
Se	Se(IV), Se(VI), dimethyl selenide (593-79-3), dimethyl diselenide (7101-31-7)	29

Pb	Plumbane (15875-18-0), trimethyllead hydride (7442-13-9), monoethyllead hydride (30691-92-0), diethyllead hydride, triethyllead hydride, tetraethyllead	32
Ge	Germane (7482-65-2), monomethylgermanium hydride (1449-65-6), dimethylgermanium hydride (1449-64-5), trimethylgermanium hydride (1449-63-4)	33

Table 5 Chemical speciation by HPLC coupled to AAS using HG

Element	Chemical species	Ref.
As	Arsenous acid (13464-58-9), arsenic acid (7778-39-4), monomethylarsonic acid (124-58-3), dimethylarsinic acid (76-60-5), *o*-arsanilic acid (2045-00-3), *p*-arsanilic acid (98-50-0), arsenobetaine (64436-13-1), arsenocholine (39895-81-3)	36
Se	Selenous acid (7783-00-8), selenic acid (7783-08-6), selenomethionine (1464-42-2), selenoethionine (6810-64-6), selenocysteine (3614-08-2)	37
Sb	Antimonous acid (13453-11-7), antimonic acid (12712-36-6)	38

High-performance liquid chromatography (HPLC) can be coupled to AAS, ICP/AES and ICP/MS to separate both volatile and nonvolatile species. Samples to be speciated by HPLC are extracted with water-soluble solvents such as methanol (67-56-1) and purified by centrifugation. The effuluents from HPLC are decomposed and hydridized with SBH. Table 5 shows some examples of chemical speciation by HPLC coupled with AAS using HG.

There are several review articles on chemical speciation by HG in spectroscopic analysis. Szpunar-Lobinska et al. included the HG technique in their speciation review.[39] Nakahara described chemical speciation by HG spectroscopic analysis[40] and Tao included the HG technique in his ICP/MS speciation review.[41] Ethylation with sodium tetraethylborate is also used for the speciation[42] of metals and organometallics.

2.2 Hydride Generation for Inductively Coupled Plasma Atomic Emission Spectrometry

2.2.1 Apparatus for Hydride Generation Inductively Coupled Plasma Atomic Emission Spectrometry

In ICP/AES, the hydrides are separated from the solution and swept continuously into an argon (8007-14-5) plasma in an ICP atomic emission spectrometer in a similar way to the continuous-flow method in AAS. Since the temperature of the plasma is much higher than that of the quartz cell in AAS, the plasma can be extinguished by ignition of hydrogen (1333-74-0) evolved as a by-product. Hence the instrumental parameters in ICP/AES should be optimized to prevent the plasma from being extinguished. Figure 4 shows a typical HG apparatus for ICP/AES.[43] ICP torches should be cleaned with concentrated nitric acid or aqua regia in a tall beaker after several uses.

2.2.2 Detection Limits and Ranges

The detection limits for ICP/AES range from parts per billion to parts per trillion as shown in Table 2. The dynamic ranges are broad.

2.2.3 Interferences

Interferences in ICP/AES[44] are similar to those in AAS. Therefore, the interferents are treated in a similar manner to those in AAS.

2.2.4 Environmental Sample Preparation for Hydride Generation Inductively Coupled Plasma Atomic Emission Spectrometry

Samples in ICP/AES are treated in a similar way to those in AAS.

Figure 4 Schematic diagram of the continuous-flow hydride generator in ICP/AES. (Reproduced from T. Nakahara, *Appl. Spectrosc*, **37**(6), 539–545 (1983) by permission of the Society of Applied Spectroscopy.[43])

2.2.5 Chemical Speciation by Inductively Coupled Plasma Atomic Emission Spectrometry

HPLC is also coupled to ICP/AES. Table 6 shows some examples of HPLC coupled to ICP/AES using HG. Figure 5 shows a schematic diagram of the HPLC system in HG/ICP/AES.[45] Effluents from a high-performance liquid chromatograph are decomposed, hydridized and swept into the torch of an ICP atomic emission spectrometer.

2.3 Hydride Generation for Inductively Coupled Plasma Mass Spectrometry

2.3.1 Apparatus for Hydride Generation Inductively Coupled Plasma Mass Spectrometry

The HG apparatus for ICP/MS is similar to that for ICP/AES. Figure 6 shows a typical hydride introduction system to an ICP mass spectrometer.[48] The ICP torch positions are optimized by sweeping a hydride-forming element not to be determined. The torches should be cleaned in the same way as described for those in ICP/AES. Sampling and skimmer cones are cleaned by warming in 0.1% nitric acid after several uses.

2.3.2 Detection Limits and Ranges

The detection limits for ICP/MS are the lowest and range from parts per trillion to parts per quadrillion, as shown in Table 2. However, the sensitivity is restricted by contamination from the reagent blanks during the preparation of standard and sample solutions. Ultrahigh-purity reagents should be used to minimize the reagent blank.

2.3.3 Interferences

Chemical interferences in ICP/MS are the same as those in AAS and ICP/AES.

Hydrochloric acid is usually used to stabilize the hydride-forming elements in dilute standard solutions and to prepare sample solutions. However, the signal of

^{75}As has an isobaric interference with $^{40}Ar^{35}Cl$, as shown in Table 7. Nitric acid is used instead of hydrochloric acid to avoid the overlap of signals in a quadrupole mass spectrometer. Selenium is determined by measuring the intensity ratio of its isotopes in a quadrupole mass spectrometer, since it has several isotopes and isobaric interferences, as shown in Table 8. The isobaric interference of ^{75}As with $^{40}Ar^{35}Cl$ can be resolved in a high-resolution mass spectrometer. Further, the signal of

Table 7 Interferences of arsenic with main isobars in ICP/MS

Isobar	Mass number	Abundance ratio[a]	Resolution

^{80}Se	79.916 521	49.7	
$^{40}Ar_2$	79.924 766	99.2	−9 693.23
^{82}Se	81.916 709	9.2	
$^{65}Cu^{17}O$	81.926 923	0.01	−8 020.54
$^{40}Ar_2H_2$	81.940 146	–	3 455.38
^{82}Kr	81.913 483	11.6	25 392.9

[a] The abundance ratios of molecules were calculated by multiplying both atom percentages in elements from IUPAC.[49]

Figure 7 Separation of the ^{82}Se signal from a $^{40}Ar_2H_2$ band. (Reproduced from H. Narasaki, J.-Y. Cao, *Anal. Sci.*, **12**(8), 623–627 (1996) by permission of The Japan Society for Analytical Chemistry.)

^{82}Se can be resolved graphically from a $^{40}Ar_2H_2$ broad band in a high-resolution mass spectrometer as shown in Figure 7.[50] A silicone-rubber tubular membrane gas–liquid separator has been introduced to avoid signal overlaps as shown in Figure 8.[51] The separator removes any vapor of chlorides (16887-00-6) and allows arsenic and selenium of masses 75 and 77 to be separated.

Figure 8 Schematic diagram of the membrane gas–liquid separator. (Reproduced from S. Branch, W.T. Corns, L. Ebdon, S. Hill, P. O'Neill, *J. Anal. At. Spectrom*, **6**(3), 155–158 (1991) by permission of The Royal Society of Chemistry.)

2.3.4 Environmental Sample Preparation for Hydride Generation Inductively Coupled Plasma Mass Spectrometry

The concentrations of acid and SBH solutions used in HG/ICP/MS should be diluted to approximately one tenth of those in HG/ICP/AES. The introduction of large amounts of water vapor and nonvolatile salts into the vacuum system should be avoided. The ion multiplier (detector) of an ICP mass spectrometer deteriorates as a result of the accumulation of salts. Evolution of hydrogen by HG should be minimized to maintain a stable plasma, since combustion of large amounts of hydrogen gas damages the plasma torch by its heat.

2.3.5 Chemical Speciation by Hydride Generation Inductively Coupled Plasma Mass Spectrometry

HPLC is coupled either directly or via hydridization to ICP/MS. The latter technique is very sensitive. Table 9 shows some examples of chemical speciation by HPLC coupled to ICP/MS using HG. Effluents from a high-performance liquid chromatograph are decomposed, hydridized and swept into the torch of an ICP mass spectrometer. Capillary electrophoresis (CE) is combined with ICP/MS owing to its sensitivity. HG/CE/ICP/MS is used for speciation of arsenic with a microporous membrane,[53] since the volume of effluents from CE is in the nanoliter range.

Table 9 Chemical speciation by HPLC coupled to ICP/MS using HG

Element	Chemical species	Ref.
Se	Se(IV), Se(VI), selenomethionine, selenoethionine	46
Sb	Sb(III), Sb(V)	38
Pb	Pb(II), tetramethyllead chloride (75-74-1), tetraethyllead chloride (78-00-2)	52

ACKNOWLEDGMENTS

I express my gratitude to the following persons who made valuable comments: Masahiko Tachibana, Department of Chemistry, Faculty of Science, Saitama University, Taketoshi Nakahara, Faculty of Engineering, Osaka Prefectural University and Kiyotaka Ishii and Kouichiro Outsuka, Japan Electron Optics Laboratory, Tokyo, Japan.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectrometry
CE	Capillary Electrophoresis
FAAS	Flame Atomic Absorption Spectrometry
GC	Gas Chromatography
HG	Hydride Generation
HPLC	High-performance Liquid Chromatography
ICP	Inductively Coupled Plasma
ICP/AES	Inductively Coupled Plasma Atomic Emission Spectrometry
ICP/MS	Inductively Coupled Plasma Mass Spectrometry
MS	Mass Spectrometry
SBH	Sodium Tetrahydroborate(III)

In the 1980s, several Program Offices of the United States Environmental Protection Agency (USEPA) investigated the use of immunoassay methods for environmental applications with limited success. Most of the problems were with method ruggedness, i.e. they worked well in clean spiked matrices, but not very well on real world samples. The situation changed significantly in January of 1992, when the Office of Solid Waste (OSW) received its first rugged immunoassay method (for pentachlorophenol (PCP)) that worked on field samples. Several more followed, and through the early and mid-1990s, the USEPA initiated use of immunoassay methodology in its hazardous waste program. The first group of methods incorporated into the OSW's methods compendium, Test Methods for Evaluating Solid Waste*, or SW-846, between 1993 and 1995 were a group of 10 enzyme-linked immunosorbent assay (ELISA)-based screening methods for various environmental analyte classes. These methods were officially 'approved' by the USEPA in July, 1997. We provided a great deal of training on these methods to raise the comfort level of the environmental community for their use.*

This chapter addresses several major topics including an overview of the USEPA's major Regulatory Programs; how analytical methods are used in Regulatory Programs; general guidelines for the development of screening methods; specific validation criteria for immunoassay methods; the current status of the USEPA immunoassay method development program; current and potential environmental applications for immunoassay technology; barriers to implementation of immunoassay methods and the steps being taken to overcome them; and future directions and new developments in immunoassay technology for regulatory programs.

The overall future of the technology for environmental monitoring and analysis looks very bright. It offers a cost effective way to generate reliable information upon which to base sound environmental decisions.

1 INTRODUCTION

Immunoassay technology has several attributes which make it a useful tool for environmental monitoring, e.g. selectivity, sensitivity, portability, and rapid turnaround time. Immunoassay kits can be tailored to target specific analytes or classes of analytes, thus eliminating the need for cleanup methods in most cases to remove interferences. They also have the capability of detecting

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

target analytes at very low levels, which are needed in many environmental applications. The portability of immunoassay test kits and speed of analysis allows for rapid analyses to be run on a site in the field. This capability can be especially useful in lowering the costs of cleanup projects because equipment does not have to lay idle while awaiting the results of laboratory analyses.

The USEPA has been looking at the potential use of immunoassay technology for environmental monitoring for several years. The early methods development efforts were unsuccessful because the immunoassay chemistry utilized in the methods was not sufficiently rugged for use on real world environmental matrices. The methods performed well on clean water matrices and spiked samples, but did not perform effectively on natural environmental samples. Because of this poor initial performance on real samples, USEPA Program Office interest in the technology declined.

In January 1992, EnSys, Inc. demonstrated a viable immunoassay test kit for PCP in both soil and water matrices to USEPA's OSW. Since that time, OSW has been working with several manufacturers to develop and validate a whole battery of immunoassay test kits both for individual analytes and for classes of analytes. The first series of immunoassay methods adopted by OSW for inclusion in its methods manual, *Test Methods for Evaluating Solid Waste*, (SW-846),[1] used ELISA as the technique of choice. Currently, OSW has issued more than fifteen immunoassay methods using several different techniques, which can be used for analyses performed under the Resource Conservation and Recovery Act (RCRA).[2]

2 BACKGROUND AND HISTORY

2.1 Overview of United States Environmental Protection Agency Regulatory Programs

2.1.1 Organization

The USEPA is not a single entity. It consists of several regulatory Program Offices which have the responsibility for implementing the major environmental laws passed by the US Congress, as well as several administrative and technical offices which support these regulatory Program Offices. These regulatory Program Offices include the Office of Solid Waste and Emergency Response (OSWER), the Office of Water (OW), the Office of Prevention, Pesticides and Toxic Substances (OPPTS), and the Office of Air and Radiation (OAR).

The various regulatory Program Offices were established at different times in response to Congressional mandates establishing the major environmental laws. These laws are very general in nature, and the USEPA regulatory program offices were formed to set-up the specific regulations needed to administer and enforce these environmental laws. Approaches to regulatory requirements and philosophy vary greatly among the regulatory Program Offices, because of the significant differences in their areas of responsibility. For example, regulations governing air and water, dealing with single media, are necessarily different than those dealing with the management of solid and hazardous waste, which involve a wide variety of media.

2.1.2 Programmatic Regulatory Responsibilities

OSWER is responsible for administering the RCRA through its OSW and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), also known as Superfund, through its Office of Emergency Response and Remediation (OERR). The OW administers the Clean Water Act (CWA) and the Safe Drinking Water Act (SDWA). The OPPTS administers the Toxic Substances Control Act (TSCA) and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), while the OAR administers the Clean Air Act (CAA). The Office of Administration and Resource Management (OARM) provides administrative support while the Office of Research and Development (ORD), along with several other non-regulatory program offices provide technical support to the regulatory Program Offices.

2.1.3 Regulatory Analytical Methods

The administration of these USEPA regulatory programs involves compliance monitoring, which utilizes a wide variety of analytical methods and techniques. This section of the chapter will focus on the similarities and differences only between the OSWER and OW monitoring programs.

The OSW regulates the management of solid and hazardous waste under RCRA. This includes regulations on generation, storage, and treatment of wastes and waste residuals from active management sites. Most RCRA applications involve site-specific analyses for compliance with permits or other regulations, unlike the general maximum contaminant level (MCL) requirements common to compliance with drinking water regulations. Since RCRA applications encompass a wide variety of media, including, soils, solids, sludges, organic liquids, water, stack emissions, and ambient air, OSW has historically used the performance based measurement system (PBMS) approach to sampling and analysis. This allows for the needed flexibility in matrix-specific and project-specific methods selection for RCRA applications.

The OSW Methods Team publishes a manual of analytical methods applicable for use in the RCRA

Program, *Test Methods for Evaluating Solid Waste*, SW-846. SW-846 functions primarily as a guidance document. In most cases under RCRA, analyses may be performed using either SW-846 methods or any other method that may be appropriate, since RCRA regulations usually only specify what the analytical requirements are, and not specifically how to do them. Whichever methods are selected, the analyst must demonstrate their applicability for their intended use. This can be done by using a two-tiered demonstration of proficiency: 1) the analyst must demonstrate the ability to perform the method and obtain acceptable results in a 'clean' matrix, such as reagent water or Ottawa sand; and 2) the analyst must demonstrate that the method will give acceptable performance in the actual matrix of concern.

However, there are a very few instances in the RCRA regulations where SW-846 analytical methods, in general, must be used to characterize waste. Because of these few cases which require the use of SW-846 methods, all new and revised methods which are included in SW-846 must be published as regulations. OSW is currently working on a regulation under the 'Reinvention of Government' guidelines to eliminate this requirement and to publish SW-846 methods as guidance as was the original intent of the manual. Methods which will not become guidance are the 'method-defined parameters', or methods which directly define regulatory requirements, e.g. flash point, corrosivity.

The OERR, on the other hand, deals with the cleanup of abandoned waste sites under CERCLA (Superfund). Most Superfund analyses are performed using the same multimedia PBMS approach as is used for RCRA. Some Superfund analyses are performed under specific contracts which can use any method deemed appropriate for the application. However, when Superfund methods are written into their contract format, they are very detailed and must be performed as written. Changes or modifications are generally not permitted.

The OW, for compliance with both the CWA and SDWA, is required to publish lists of both regulated and unregulated target analytes and to publish approved methods for the analyses of these analytes. Use of alternative methods is not permitted, unless a method equivalency petition is requested by a petitioner and granted by USEPA or other designated authority.

Thus, of the four major USEPA Program Offices for which substantial numbers of analyses are performed, RCRA offers the most flexibility as to choice and application of analytical methods. RCRA only specifies what the analytical requirements are, and leaves the decision as to how the analyses are to be performed to the analyst.

2.2 Developmental History of Immunoassay Methods in United States Environmental Protection Agency Programs

While several USEPA Program Offices investigated the potential applicability of immunoassay methods to their programs, OSW is the first USEPA Program Office to formally incorporate these techniques into its methods program. OSW has taken the Agency lead in developing new immunoassay techniques for its own methods program and is actively working with other USEPA Program Offices to assist them in developing immunoassay methods for their programs.

OSW began evaluation of its first immunoassay method (for PCP) in January 1992, followed by three others in rapid succession. By July 1995, OSW had completed validation of a general overview method and ten individual immunoassay methods (with more than 25 different kits) utilizing ELISA, and published them in the proposed Update III of SW-846. For a USEPA regulatory Program Office, this is very rapid progress. These immunoassay methods covered the analysis of PCP, polychlorinated biphenyls (PCBs), polynuclear aromatic hydrocarbons (PAHs), petroleum hydrocarbons, pesticides and explosives. See Table 1 for a list of these methods. OSW formally approved the first immunoassay method, for PCP, as part of a January 1994, regulation. The rest of the methods in Table 1 were formally approved as part of Update III to SW-846 in June, 1997. All of these methods can be used for any RCRA application for which they can be demonstrated to work.

Between late 1995 and late 1997, the environmental immunoassay industry fell on hard times due to severe cutbacks in remediation projects for which there was a major potential market for use of these environmental immunoassays. This resulted in a consolidation of the

Method 4051:	RDX Explosives in Water and Soils by Immunoassay[40,41]

2,4-D, 2,4-dichlorophenoxyacetic acid; TPH, total petroleum hydrocarbons; TNT, 2,4,6-trinitrotoluene; RDX, hexahydro-1,3,5-trinitro-1,3,5-triazine.

four major manufacturers into a single entity. While the industry was busy sorting itself out during this period, very little was happening in the area of new product and methods development. However, by the end of 1997, several new manufacturers began operating and several new products have either come on the market or are in the final stages of testing, including second generation ELISA kits for PAHs and PCBs, the first immunoassay method (ELISA for mercury) for a metal, immunosensors for explosives, and, finally a series of screening methods for dioxins and coplanar PCBs using a variety of techniques.

Some of the other USEPA Program Offices are also looking at immunoassay methods to address some of their analytical requirements. OPPTS is considering using immunoassay methods in its Pesticide Registration Program. OW is beginning to look at using the technology in both the Drinking Water and Wastewater Programs. However, they may have to revise some of their regulations to allow for the use of 'less than' values in reporting MCLs or look toward developing quantitative immunoassays.

3 TYPES OF IMMUNOASSAY TECHNOLOGIES EMPLOYED IN ENVIRONMENTAL PROGRAMS

3.1 Enzyme-linked Immunosorbent Assay

ELISA[3–10] is the most commonly used immunoassay technique for environmental analysis. The immunoassay test products available will often vary in both format and chemistry. The characteristics of a specific product are described in the package insert provided by the manufacturer. This summary is, therefore, general in scope, and is intended to provide a general description of the more common elements of these methods.

Immunoassay test products use an antibody molecule to detect and quantitate a substance in a test sample. These testing products combine the specific binding characteristics of an antibody molecule with a detection chemistry that produces a detectable response used for interpretation. In general, antibody molecules specific for the method's intended target are provided at a predefined concentration. A reporter (i.e. signal generating) reagent, composed of the target compound conjugated to a signal producing compound or molecule (e.g. enzymes, chromophores, fluorophores, luminescent compounds, etc.), is also provided. The concentration, affinity, and specificity of the products' antibody influences performance, as does the chemistry of the reporter reagent.

The reporter reagent and antibody molecules of a given product are binding partners, and form a complex in solution. The addition of a positive sample containing the target substance to this solution results in a competitive binding reaction between the target analyte and the reporter reagent for the antibody sites. The antibody concentration, and therefore binding capacity, is limited to prevent the simultaneous binding of both the reporter and target molecules. The concentration of reporter reagent that can bind to the antibody is inversely proportional to the concentration of substance in the test sample.

Immunoassay methods may be heterogeneous (i.e. requiring a wash or separation step), or homogeneous (i.e. not requiring a separation step). In commonly available heterogeneous testing products, the antibody is immobilized to a solid support such as a disposable test tube, and the bound reporter reagent will be retained after removing the unbound contents of the tube by washing. Therefore, a negative sample results in the retention of more reporter molecules than a positive sample. The analysis of a standard containing a known concentration results in the immobilization of a proportional concentration of reporter reagent. A positive sample (i.e. containing a higher concentration than the standard) results in the immobilization of fewer reporter molecules than the standard, and a negative sample (i.e. containing less than the standard) will immobilize more.

A chemistry of the detection of the immobilized reporter is used for interpretation of results. The reporter molecule may be a conjugate of the target molecule and a directly detectable chromophore, fluorophore, or other specie, or conjugated to an enzyme that will act upon a substrate to produce the detectable response. Immunoassay testing products have a quantitative basis, and will produce a signal that is dependant on the concentration of analyte present in the sample. For environmental immunoassay methods, the signal produced is exponentially related to the concentration of the compounds present. Many immunoassay methods use enzymes to develop a chromogenic response, and are termed enzyme immunoassays. Assays that generate a chromogenic response are analyzed photometrically, and use the principles of Beer's law (absorbance = extinction coefficient $\times$ concentration $\times$ pathlength) to determine the concentration of analyte in a sample.

Immunoassay methods can provide quantitative data when configured with a series of reference standards that are analyzed and used to construct a standard curve. The signal generated from the analysis of a test sample is used to determine concentration by interpolation from the standard curve. Alternatively, these testing products can be configured to determine if a sample is positive or negative relative to a single standard.

Individual immunoassay testing products are reviewed and accepted by the USEPA OSW for the detection of sample analytes in specified matrices. A variety of testing products, produced by several different developers, may

be available for the same compound(s) and matrices. Each of these methods have been formulated using independently developed reagents that may result in significantly different performance characteristics and limitations.

The performance of the immunoassay testing products ultimately relates to the characteristics of the antibody, reporter molecule, and sample processing chemistry. The dose-response characteristics of a method, the position of the standard relative to the claimed action level, and the stated cross-reactivity characteristics of the selected test product, provide relevant information regarding the performance and recognition profile of the selected test product.

The precision, and ultimately the sensitivity of an immunoassay method, is a function of the signal-to-noise characteristics of its dose-response curve, and its operational consistency. Methods having a high slope and low non-specific signal generation produce the most sensitive and precise methods. Signal imprecision applied to a dose-response curve having a shallow slope exhibits proportionally greater imprecision in the calculated concentration than would a method having a steeper slope. In an action level testing product, this would cause the reference standard to be positioned further from the action level, increasing the incidence of false positive results. Similarly, a method having less non-specific signal generation (higher signal-to-noise ratio) will be more sensitive and precise when other characteristics (i.e. dose-response slope) are held constant.

Immunoassay methods are used to detect contamination at a specific concentration below the claimed detection level for the test product. For example, an immunoassay used to detect PCB contamination in soil at 1 ppm will include a standard preparation containing less than 1 ppm. The reference preparation concentration is positioned to minimize the incidence of false negative results at the claimed detection level. For remediation and monitoring applications, where action levels of interest are defined, immunoassay methods should exhibit a negligible incidence of false negative results, and minimal false positives.

For a single point action level test, the concentration of analyte relative to the action level is selected by the developer, and is influenced by the precision (i.e. intra-assay, inter-person, inter-lot, inter-day, etc.), sample matrix interferences and other performance characteristics and limitations of the basic method. The concentration of analyte in the reference materials should be less than, but close to, the claimed action level. The concentration selected for the standard defines the concentration that will produce a 50% incidence of false positive results by the test product. While this issue is one representing limited liability to the operator, it is a practical issue that often requires attention. An immunoassay method for the detection of 1 ppm of PCB using a standard containing 0.8 ppm of PCB will experience a 50% false positive incidence in samples containing 0.8 ppm of PCB, and some incidence of false positive results in a sample containing between 0.8 and 1 ppm. A similar immunoassay that uses a standard containing 0.4 ppm will experience a 50% false positive incidence in samples containing 0.4 ppm of PCB, and some incidence of false positive results in a sample containing between 0.4 and 1 ppm. The closer the standard concentration is to the action level, the better the overall performance.

Cross reactivity characteristics illustrate the specificity of the underlying immunochemistry. The antibody molecules used by a test product bind to a target compound and then participate in the process of generating the signal used for interpretation. Antibody molecules bind by conformational complimentarity. These molecules can be exquisitely specific, and can differentiate subtle differences in the structure of a compound. The binding characteristics of reagents in different test products can vary, and influence the recognition profile and incidence of false results obtained by the method. Immunoassay methods should detect the target analytes claimed by the test product and exhibit limited recognition for compounds and substances not specified.

3.2 Reporter Gene on a Human Cell Line

The reporter gene system[42–50] utilizes a human cell line (101L) into which a plasmid containing a human CYP1A1 promoter and 5′-flanking sequences fused to a reporter gene, firefly luciferase, have been stably integrated. In the presence of CYP1A1-inducing compounds, the enzyme luciferase is produced, and its reaction with luciferin can be detected by measuring relative light units (RLUs) in a luminometer. CYP1A1-inducing environmental contaminants include polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), coplanar PCB congeners, and high molecular weight PAHs.

To quantify the inducing compounds in the sample, the mean response, in RLUs, of the three sample replicates is divided by the mean response of three replicates of a solvent blank, yielding a 'fold induction', which is a measure of the increase of the sample response over the background response. Fold induction may be converted to toxic equivalents (TEQ) for PCBs and PCDDs/PCDFs, or benzo[*a*]pyrene equivalents (B[*a*]PEqs) for PAHs, based on the fold induction responses to standards containing a mixture of PCDDs/PCDFs, or benzo[*a*]pyrene, respectively.

This method can be used to estimate the concentrations of PAHs and/or coplanar PCBs in soils over a range from 0.1 to over 100 mg kg^{-1}. In addition, the presence

of PCDDs/PCDFs in the extract will be indicated at concentrations ranging from 100 ng kg^{-1} to over 1 mg kg^{-1}. These sensitivity estimates are based on the extraction of 40-g solid samples and evaporation of the extract to 1 mL, with the application of 20 μL to one million cells covered by 2 mL of medium. The sensitivity of the method for water samples is approximately 25 times greater, assuming that a 1-L water sample is extracted and the extract is concentrated to the same 1-mL volume (e.g. 4 μg L^{-1} to 4 mg L^{-1} for PAHs and PCBs, and 4 ng L^{-1} to 40 μg L^{-1} for PCDDs/PCDFs).

The method contains an optional procedure in which exposures are conducted over two specific time periods (6 and 16 hours). This option allows the test to distinguish between PAHs in the samples and chlorinated compounds, since the PAHs reach maximum induction at 6 hours, while the peak in induction from chlorinated planar compounds (PCBs, PCDDs/PCDFs) is not until 16 hours.

This method is a screening procedure, and depending on project needs. A subset of the samples should be confirmed using quantitative analytical techniques.

3.3 Immunosensors

Two types of immunosensor techniques have been evaluated at this time,[51–68] both of them for TNT and RDX explosives. The first, a flow cell technique is based on performing a fluorescent displacement immunoassay on a membrane or other solid support in flow. Antibodies immobilized on a solid support (i.e. membrane) are saturated with a fluorescent analog of either TNT or RDX. A test sample is injected into the flow stream. If the appropriate analyte (TNT or RDX) is present in the test sample, it will displace a proportional amount of fluorescent analog. The displaced analog is detected downstream. The fluorescent signal is proportional to the concentration of the analyte in the test sample. This technique can be used as a screening tool to determine if TNT or RDX is present above a critical limit or for quantitation of the explosive in the test sample. To quantitate, the area of the fluorescent peak is compared to standards tested pre and/or post test sample. Results obtained with this method can be used to identify samples with TNT and RDX concentrations between 10 and 1200 ppb.

The second, a fiberoptic technique, is based on performing a competitive fluorescent immunoassay on the surface of a fiber optic probe. A fluorescent analog of either TNT or RDX is added to the test sample. The sample is then passed over optical probes which have antibodies immobilized on the surface which are specific for either TNT or RDX. A decrease in maximum fluorescence proportional to the concentration of TNT or RDX in the sample is observed. This technique can be used as a screening tool to determine if TNT or RDX is present above a critical limit or for quantitation of the explosive in the test sample. To quantitate, the percent inhibition is compared to a standard curve. Results obtained with this method can be used to identify samples with TNT and RDX concentrations between 5 and 200 ppb.

3.4 Affinity Chromatography

Affinity chromatography is a potential sample preparation technique whereby the selective nature of immunoassay methods, particularly ELISA, can be used to extract specific compounds or compound classes out of a difficult matrix. The bound analytes can then be desorbed and analyzed by an appropriate chromatographic or other determinative technique, e.g. high-performance liquid chromatography (HPLC).

3.5 Dissociation-enhancement Lanthanide Fluoroimmunoassay

The DELFIA (dissociation-enhancement lanthanide fluoroimmunoassay) methodology was developed by scientists at EG&G Wallac, Turku, Finland and the Department of Molecular Endocrinology of Middlesex Hospital, London.[84] This method is clinically proven and is highly reliable and adaptive. The DELFIA system is based on time-resolved fluorometry of lanthanide compounds such as europium. Lanthanide ions exhibit a unique fluorescence that is characterized by narrowband emission lines, a long decay time, and large Stokes shift. The specific fluorescence of the lanthanide label is measured after a certain time delay following an activation pulse allowing all of the nonspecific background to expire. The DELFIA system and instrumentation allows the detection of four different toxicants in one sample by using four different lanthanide labels each having a distinctive fluorescence spectrum.

4 METHOD DEVELOPMENT

4.1 General Guidelines for Development of Screening Methods

The primary applicability that we, in the RCRA Program, see for immunoassay methods is for quantitative screening purposes.[69] By quantitative screening, we mean setting a quantitative action level (usually the regulatory action level), where a positive response means that the analyte is present at or above the action level, and a negative response tells us that the analyte is either absent or present below the level of regulatory concern. Analyses can be run at multiple action levels giving a useful range of concentrations for specific target analytes.

For example, if we are mapping a site contaminated with PCBs to determine the extent to which it needs to be cleaned up, knowing where PCB levels are <10 ppm, between 10 and 100 ppm, and >100 ppm can be useful in planning and expediting the cleanup.

The OSW Methods Team provides a guidance document (available on-line at http://www.epa.gov/SW-846) to potential developers of screening methods providing guidance on what general validation criteria should be applied to a screening method that will potentially be included in SW-846. While screening procedures need not be fully quantitative, they should measure the presence or absence of target analytes at or below regulatory action levels. Therefore, initial demonstration of method performance involves measuring the percentage of false negatives and false positives generated using the procedure for a single sample matrix. Data should be submitted for split samples analyzed using the developer's technique and an appropriate SW-846 quantitative method. A candidate procedure should ideally produce no false negatives. Definition of a false negative is a negative response for a sample that contains the stated detection level of the target analyte(s). A candidate procedure should produce no more than 10% false positives. Definition of a false positive is a positive response for a sample that does not contain analytes at the detection level. Between 20 and 50 samples spiked at the detection level should be tested to establish the percentage of false positives. Between 20 and 50 samples spiked at the detection level should also be tested to establish the percentage of false negatives. It is recommended that a sufficient volume of each spiked sample be prepared to complete each test with one lot of material. Sufficient randomly selected aliquots of each spiked matrix should be analyzed by appropriate SW-846 methods to demonstrate sample homogeneity and to characterize the sample in terms of target analytes and potential interferences.

A separate study should also be conducted to establish the effect of non-target interferences. A screening procedure should produce no more than 10% false positives for a set of 20 samples that contains a 100 fold excess of interferences. Positive interferences should be selected that are chemically related to the target analytes and are environmentally relevant. Negative interferences (i.e. masking agents) should also be investigated whenever they are suspected.

Developers should also analyze three different types of samples to provide matrix-specific performance data. These samples should either be characterized reference materials or spiked matrices containing known amounts of target analytes. In either case, bulk samples should be carefully homogenized to reduce sub-sampling errors. The sample matrices should be selected to represent what is regulated under RCRA (e.g. soil, oily waste or wastewaters), not to provide the best performance data. Blanks should be analyzed with each set of samples.

Matrix-specific performance data, including detection limits and dynamic range, are gathered by analyzing ten replicate aliquots of three different sample matrices spiked at two concentrations. If spiked samples are used, suggested spiking levels are the matrix-specific detection limit and 50 times the detection limit. Positive or negative results should be reported for the low concentration samples. Results for high concentration samples should be reported as either semi-quantitative results or as positive/negative with the dilution factor used for the samples. As an alternative to establishing matrix-specific detection limits, specific spiking concentrations are provided for selected target analytes in the guidance document. The low values are normal reporting limits for routine analyses and the high value is 50 times the low concentrations. The Methods Team recognizes that it may not be appropriate to spike all of the target analytes listed within a chemical class.

If the developer has field data, the Methods Team would welcome the opportunity to compare the results obtained using the screening procedure with sample concentrations determined in a laboratory using SW-846 or other appropriate methods.

To summarize, the Methods Team does not require an unreasonable body of data for the initial evaluation of new techniques. Data will need to be submitted on the percentage of false negatives, percentage of false positives, sensitivity to method interferences, and matrix-specific performance data. In addition to these data, the developer should also provide a description of the procedure and a copy of any instructions provided with the test kits.

4.2 Validation Criteria for Immunoassay Methods

4.2.1 Screening Methods

In addition to the guidelines for developing screening methods in general, OSW, based on its own experience, has generated some validation criteria specifically applicable to immunoassay methods.[70,71] These validation criteria, based on the United States Food and Drug Administration (USFDA) 510 K guidelines, are required to be submitted to OSW for review for all immunoassay test kits, whether the kits are to be the basis for a new method or as an alternative kit being added to existing methods. The data needed for validation of immunoassay methods that will be included directly in the method is as follows:

1. cross reactivity with similar analytes;
2. cross reactivity with dissimilar analytes which may be reasonably expected to be found at waste sites;
3. false negative/false positive rates;

4. extraction efficiency (for soil test kits);
5. performance data on spiked samples in environmental matrices validated against standard SW-846 analytical methods;
6. performance data on actual environmental field samples validated against standard SW-846 analytical methods.

Since interferences can be a major problem in environmental analyses, it is important to demonstrate that the analytes of concern can be identified in the presence of similar analytes or dissimilar analytes which may be present in environmental samples. In many instances, substantial cross reactivity with other analytes is a desirable situation. Examples of desirable cross reactivity include sensitivity to esters of 2,4-D as well as the 2,4-D, and for other 3-, 4-, and 5-membered PAHs when testing for phenanthrene in a PAH screening method.

The false negative/false positive rate for a particular immunoassay kit is very important. OSW screening methods are designed to generate 0% false negatives and up to 10% false positives at the regulatory action level. Slightly higher false positive rates are tolerable, e.g. up to 25%. High false positive rates, i.e. >25%, negate the cost effectiveness of the technique because of the excessive numbers of confirmatory tests that would need to be performed. High false negative rates, i.e. >5% at the regulatory action level eliminate the potential use of the method for regulatory purposes.

The extraction efficiency data are important for setting the appropriate action level for a soil analysis. Recoveries are the primary determining factor for making sure that the analyte of concern can be detected at the regulatory action level and for minimizing false negative/false positive rates. Extraction efficiencies need not be quantitative, because of the sensitivity of the antibodies used. However, they must be consistent and reproducible.

The performance data generated from environmental samples spiked with the target analytes give a good indication as to whether or not an immunoassay method will work. However, the performance generated in the field on real environmental samples is the key determining factor on whether or not the immunoassay method is sufficiently rugged to be included in SW-846 as an analytical method.

Additional data that OSW requests, but does not include in the method and treats as confidential business information (CBI), includes dosage curves and the manufacturer's internal validation and quality control criteria. The slope of the dosage curve can be a good indication of whether or not an immunoassay method will exhibit a high rate of false positives.

Up to this time, all of the immunoassay test kits (>25) that the OSW has evaluated have been extensively tested and validated by the manufacturers. USEPA validation has primarily consisted of confirmation of the manufacturers' results and performing some additional testing on well-characterized environmental samples, which are more easily available to USEPA regional laboratories.

4.2.2 Quantitative Methods

OSW has issued a guidance document for the validation of quantitative methods, ''Guidance for Methods Development and Methods Validation for the RCRA Program'',[69] describing the key elements that need to be met from the Proof of Concept stage through single and multilaboratory validation. The document is also available on the Internet from the OSW Methods Team Homepage at ''http://www.epa.gov/SW-846''. Quantitative immunoassay methods would be validated using the same criteria as any other quantitative method.

4.2.3 Revalidation Issues

Based on the successful incorporation of ten immunoassay methods involving more than 25 validated individual test products, the issue has come up as to what type of revalidation of a previously validated method is necessary if that method is changed. Once again, we defer to the USFDA for guidance on this issue. The guidelines that will be included in the revised Immunoassay Screening Methods Development Guidance Document are that for non-substantive changes, i.e. changes that do not affect the basic chemistry of the method, no revalidation will be necessary. An example of this type of change would be change of an inert washing solution in an ELISA kit.

If the manufacturer decided to change the format of the product, e.g. from a tube reaction to a home pregnancy test kit type format without changing the chemistry, the manufacturer would need to do a partial revalidation. This partial revalidation would need to be sufficient to demonstrate that the format change has not adversely affected or changed the chemistry and that the new kit gives the same results as the old one on split samples.

If the manufacturer changes the chemistry in an existing product, this would be considered as a new product and would require a new validation.

5 STATUS OF THE UNITED STATES ENVIRONMENTAL PROTECTION AGENCY IMMUNOASSAY METHODS DEVELOPMENT PROGRAM

5.1 Current Validated Methods

The first eleven immunoassay methods (see Table 1) were formally approved for incorporation into SW-846

by regulation in June, 1997. The generic Immunoassay method (Method 4000) and the ten individual ELISA methods may be used for any analytical application for which they can be demonstrated to be appropriate. No regulatory barriers remain to prevent the use of these methods.

The five new methods included in Table 2 have been formally validated and accepted by OSW's Technical Workgroup. However, until the regulations removing the requirements to adopt new methods through regulatory action are removed (expected to be completed by the end of 2000), the use of these methods may be limited by some regulatory restrictions. However, for most of the applications for which they are intended to be used, there are no actual regulatory barriers, only perceptions.

Method4425, developed by Columbia Analytical Services (CAS),[42–50] is a gross screening method using a reporter gene on a human liver cell line to screen for PAHs, PCBs and dioxins. The method can distinguish between PAHs and chlorinated compounds by differences in reaction time. The method can give useful semiquantitative information only on well characterized sites in the monitoring mode.

Method 4500, developed by BioNebraska,[72,73,92] is the first USEPA immunoassay method for a metal, mercury. It provides semiquantitative screening data for mercury extracted from soils with acid and followed by a colorimetric determination using ELISA.

Methods 4655 and 4656 are immunosensor probe methods for TNT and RDX explosives developed by the Naval Research Laboratory (NRL)[51–68,81,82] using previously developed ELISA antibodies used in the earlier test kit methods (see Methods 4050 and 4051 in Table 1) and detection using a flow cell technique based on performing a fluorescent displacement immunoassay on a membrane or other solid support in flow or a fiberoptic technique based on performing a competitive fluorescent immunoassay on the surface of a fiber optic probe.

Table 2 Next generation of methods validated for use in RCRA programs

Method 4425:	Screening Extracts of Environmental Samples for Planar Organic Compounds (PAHs, PCBs, Dioxins/Furans) by a Reporter Gene on a Human Cell Line[a]
Method 4500:	Mercury in Soil by Immunoassay[a]
Method 4655:	Explosives Analysis in Soil and Water Using Environmental Immunosensors[a]
Method 4656:	Explosives Analysis in Soil and Water Using Fiber-optic Immunosensors[a]
Method 4670:	Triazines as Atrazine in Water by Immunoassay[a]

[a] Draft methods. Can be used for applications where the use of promulgated SW-846 methods is not necessary.

Method 4670[74–78,80] developed by Ohmicron (SDI, Inc.) is a competitive ELISA immunoassay method for the quantitative determination of triazine herbicides as atrazine in drinking water. This method will be discussed in more detail in section 6.5.

Copies of the methods in Table 2 are available now or will be shortly on the OSW Methods Team Homepage at "http://www.epa.gov/SW-846".

5.2 Methods under Development

The six methods listed in Table 3 are in various stages of development. Methods 4025 for dioxin and 4026 for coplanar PCBs are ELISA methods from Cape Technologies and should have their validations completed by the end of 1999. The validation of the DELFIA method for dioxin TEQ, Method 4430, from Hybrizyme should also be completed around the same time. The other three methods, Method 36xx for affinity chromatography, Method 4016 for 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and Method 4060 for TCE are all only in the beginning stages of development at this time.

Dioxin is a general term that describes a group of highly toxic chemicals that are extremely persistent in the environment. These compounds have been of major interest to immunoassay method developers. There are 210 different dioxin and furan congeners, 17 of which have been determined to be toxic. Each toxic congener has been assigned a toxic equivalency factor (TEF) which expresses how biologically active it is as compared to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), the most toxic congener. Studies have demonstrated that the toxicity of the individual congeners is additive. The additive effects of these compounds are expressed as total TEQ in comparison to TCDD.[85,86]

The scientific community has now identified a common pathway responsible for most, if not all, of the harmful effects associated with exposure to dioxin and related compounds. The interaction of dioxin-like compounds with a cellular protein known as the "Aryl hydrocarbon receptor" or "Ah receptor" represents the first step in a series of events that ultimately alters normal physiological processes.[87] Exposure to dioxin-like molecules has been

Table 3 New methods under development

TCE, trichloroethylene.

linked to a variety of illnesses including cancer, harmful reproductive and developmental effects, immunotoxicity, diabetes, and endometriosis.[88]

Discovery of the Ah receptor provided a key to understanding the molecular mechanism of dioxin toxicity. The Ah receptor resembles the broad category of steroid hormone receptors and like those receptors, it regulates gene transcription. The receptor is capable of a high degree of structural discrimination between molecules and of transducing signals at very low concentrations. The toxicity of the 17 dioxins and furans results from changes in the expression of critical genes following binding and activation of the Ah receptor. Therefore, biological systems respond to the cumulative exposure of Ah receptor-mediated chemicals rather than to the exposure to any single dioxin-like compound, thus providing the molecular basis for the empirically derived TEF and TEQ value system.[89]

Several different approaches have been used for screening of toxic dioxins and furans by immunoassay. These include the reporter gene approach (Method 4425) described in the previous section, ELISA (Method 4025) and DELFIA (Method 4430).

Cape Technologies' Method 4025 (ELISA) is a screening method that measures TEQ of dioxins and furans in soil and water extracts. It does involve a detailed sample preparation procedure, unlike the test kits for simpler target analytes. Therefore it is more suitable for laboratory use than for field use. The method is readily sensitive to 500 ppt TEQ in soils.[90]

Hybrizyme's dioxin assay (Method 4430) is based upon a recombinant version of the Ah receptor gene which is used in the assay to accurately measure dioxin-like compounds. The DNA sequence adjacent to the Ah receptor gene has been modified so that the recombinant protein can be manufactured in large quantities and easily incorporated into an immunoassay format. Accordingly, the assay embodies 'nature's perfect device' for detecting the presence of these compounds and provides the user with a 'risk-based' approach to TEQ analysis. In conjunction with the Ah receptor-based assay system, Hybrizyme has developed sample processing procedures that will allow the test to selectively detect dioxins and furans, co-planar PCBs, or carcinogenic PAHs such as benzo[*a*]pyrene.

The Method 4430 dioxin assay is noncompetitive by design. Almost all immunoassays that detect small molecules are competitive in nature. The sensitivity of noncompetitive assays increases with lower

immunoreactant concentrations since, at low concentrations, a variation in the number of competing molecules has a larger impact on the interaction with the labeled species. However, according to the law of mass action, the low antigen and antibody concentrations considerably reduce the rate of complex formation and, at very low concentrations, the accuracy tends to be poor. As a non-competitive assay, the Ah receptor test will utilize a large excess of receptor to obtain a maximum signal for the compound being tested. Even at very low concentrations of molecules, a high fraction will react if the receptor is added in excess. Although not practically achievable, the theoretical limit of the detection for this system is one molecule.[91]

The Hybrizyme DELFIA assay provides an ultra-sensitive measurement system for detecting dioxin-like molecules that interact with the Ah receptor. By utilizing molecular cloning methods and clinical instrumentation, the method provides the analytical laboratory with a product containing built-in QA/QC routines, retained standard curves, LIMS compatible data-reduction, and the ease-of-use demanded in state-of-the-art clinical laboratories.

Cape Technologies has also developed an ELISA-based immunoassay for coplanar PCBs (Method 4026)[93] similar to its dioxin immunoassay (Method 4025). The method is sensitive to the 14 dioxin-like PCB congeners and is in the process of field testing to complete the final validation for inclusion in SW-846.

5.3 List of Validated Immunoassay Test Products

Table 4 provides a list of individual immunoassay test products that have been validated by OSW and were commercially available. Due to the merger of the four major manufacturers in 1997 and a reorganization of product lines, some of the listed ELISA kits may have been discontinued.

6 ENVIRONMENTAL APPLICATIONS

6.1 Advantages and Disadvantages of Immunoassay Methods

The use of immunoassay methods provides many advantages to the analyst in solving environmental problems. Some of the significant advantages derived from using this technology include selectivity, sensitivity, portability, rapid turnaround time, improved data quality, and overall cost effectiveness. Immunoassay methods by their very nature and design are very selective in their scope of applicability, i.e. they are designed to be very specific for the analysis of either an individual compound, e.g. 2,4-D or toxaphene, or an individual class of compounds, e.g. PAHs or PCBs. Compounds other than the target analytes which may be present on a potential site do not react under the conditions and reagents used for the particular methods.

Sensitivity is another advantage of immunoassay technology. Many target analytes can be detected in the ppm range or low ppb range, if necessary. Many commercial products can be obtained or prepared to operate in several ranges, e.g. 1, 10 and 100 ppm, allowing for useful site mapping to determine which areas of a contaminated site are in need of cleanup and which are not. Some kits can operate both at the low ppb range and with appropriate dilution in the ppm range. An example is the 2,4-D kit (Method 4015) developed by Ohmicron which was designed to be sensitive to drinking water MCLs of 18 ppb, and could also be used with appropriate dilution for RCRA toxicity characteristic (TC) analysis at a 10-ppm regulatory limit.

Portability is another advantage of immunoassay technology. Most immunoassay products are sold in kit form and utilize very small apparatus, both for sample handling and in the colorimeter used for detection. Thus, it is very easy to take these kits directly to a field site for use or to an on-site mobile laboratory. However, when working directly on a field site with immunoassay methods, the operator must be very careful to follow the manufacturer's instructions on the package insert as to operating parameters, particularly with respect to effective temperature range. If the method is performed outside of the manufacturer's specified temperature range, i.e. if performed at 10 °C when the specified range is 15 °C to 30 °C, the method will not work and will give erroneous data. Most kits that are operated outside of their designated temperature range are usually designed to give positive results, i.e. potential false positives.

Rapid turnaround time is another advantage of immunoassay technology. Most samples can be run in less than an hour directly on-site. This is particularly useful in a remediation activity where soil is being removed and the site manager needs to know when the cleanup level has been achieved. At this point the excavation can be demonstrated to have been completed. This can result in a considerable cost savings over the conventional approach of sending a few samples out to a laboratory and waiting several days for the analytical results to come back. By this time, a great deal of unnecessary expenditure for excavation or equipment demurrage may have occurred.

Use of immunoassay technology can also improve the overall data quality of a remediation project. The rapid turnaround time and significantly lower cost per sample over conventional laboratory methods, e.g. gas chromatography/mass spectrometry (GC/MS) or gas chromatography/electron capture detection (GC/ECD),

can result in the ability to run a much larger number of samples during the remediation project. The data from these additional samples provide a much better characterization of the site and the progress of the remediation than would the data from the relatively few conventional samples that may normally be analyzed.

The use of immunoassay technology can be very cost effective compared to conventional technologies for all of the reasons previously mentioned in this section. However, since immunoassay methods are used primarily as quantitative screening methods, one still needs to do appropriate confirmation analysis using conventional analytical methods to support the immunoassay data. OSW recommends that approximately 5 to 10% of the immunoassay samples that generate negative results be confirmed by conventional laboratory techniques, depending on the number of total samples that are run for the particular project. Confirmation of positive samples may be done on a routine basis or as needed.

However, despite the many advantages of using immunoassay methods, there are a few disadvantages as well. The primary disadvantage is that, because they are very selective in nature, they are not effective tools for characterization of an unknown site. The most effective use of immunoassay methods is in the monitoring mode for a well-characterized site, rather than in the survey mode when one is trying to determine what compounds are the primary contaminants of the site.

Another disadvantage is that for class-specific methods, the immunoassay kit does not differentiate between the individual analytes present. Also depending on the nature of the antibody employed, the specific method may not be sensitive to all compounds within that particular class. Some of the early PAH kits (Method 4035) who had antibodies designed on phenanthrene were not particularly sensitive to PAHs containing more than four rings. An additional kit sensitive to benzo[*a*]pyrene was needed to analyze for PAHs containing 5 to 7 rings. A second generation kit with an antibody targeted to a four-membered ring (chrysene) now covers the entire range. In addition, some of the early PCB kits (Method 4020) were designed around the congeners present in Aroclor 1248 or Aroclor 1254 and did not respond well to the less chlorinated congeners found in Aroclor 1242. Thus, it is important to have a good site characterization prior to employing immunoassay methods in the monitoring mode.

Another factor of which an operator needs to be aware is the type of potential matrix interferences that may be present on a site to prevent an immunoassay method from performing. Five per cent of an oil could prevent most soil PCB kits from working, except for the one product that was specifically designed to perform in an oily matrix. Moisture levels and pH can also prevent some kits from performing as expected by the user or claimed by the manufacturer. The precautions necessary to overcome these problems are usually included on the package inserts from the manufacturers.

A peripheral issue is the extent of training necessary for an operator to become proficient in the use of the immunoassay kits. Early on, the sales push was that a minimally trained operator could take a kit, maybe read the instructions, and then go out into the field and start performing analyses. In reality, this was not the case at all. Operators need to be trained well in the nuances of handling immunoassay kits. A non-scientist, in particular, needs to be educated very intensely as to which steps in the procedure are critical and must not be changed. In the validation studies for the first 10 ELISA methods, OSW found that analytical chemists, by far, obtained the best analytical results.

6.2 Implementation Issues

There have been some initial barriers to getting immunoassay methods accepted for routine use in the environmental community. These barriers have been both technical and cultural in nature. The technical barriers include lack of knowledge about analytical options; use of expensive time-consuming methodology when more efficient methodology is available; poor planning of the initial analytical scheme; failure to identify proper questions to be answered which can result in generation of data inappropriate to address the problem at hand. Cultural barriers include inappropriate or excessive regulatory restrictions on use of new methods, e.g. requiring the use of only promulgated methods for program applications that do not have these requirements, and requiring the use of expensive broad-scope methods, e.g. GC/MS, for limited monitoring applications for only a few known and well-characterized analytes.

An additional issue of concern was whether the Regulatory Program Offices could live with analytical values that were not a specified number, i.e. a less than value (usually the regulatory action level) vs. a definite number (0.1 ppm) or a range of values (>5 and <50). We, in the RCRA Program, decided that we could indeed use these values to answer the basic questions for which these analyses were performed, i.e. Have we attained our cleanup criteria? Where do we have to focus our cleanup efforts? We decided that our normal operating procedures for confirming quantitative screening results would be to use the standard reference method to confirm positives and to spot check a certain percentage (usually 10%) of negative results.

Other Program Offices in USEPA, such as the OW may have some restrictions in their current regulations which require them to generate a definite analytical value. The

Office of Groundwater and Drinking Water (OGWDW) has decided to include quantitative immunoassay screening methods in their regulations, the first of which will be Method 4670 for triazines as atrazine. This potential application is described in section 6.5.

OSW has initiated a major effort to educate USEPA permit writers, enforcement people, and others who deal with analytical methods in their jobs as to what the regulatory aspects of using RCRA methods really are. Many of these people were not aware that RCRA regulations did not require the use of only promulgated methods for most applications. The Methods Team has developed a formal training program for RCRA personnel in the Regions and at Headquarters to make them aware of what methods the regulations really allow them to use for RCRA applications, and how to plan an efficient, cost effective sampling and analysis plan.

State programs are a little more difficult. Since RCRA is a Federal Program which has been passed down to most States to administer, the State regulations can be more restrictive and tend to vary greatly. Some States mandate the use of SW-846 methods for all RCRA analytical applications within the State. Flexibility within State Programs varies from allowing only the use of promulgated methods to using any method that may be appropriate for an application. Through dialogue with the USEPA Regions and Headquarters, some of the States are beginning to take an interest in utilizing immunoassay methods. TPHs analysis is the major focus right now in State Programs, since it is not regulated at the Federal level. Several States are beginning to adopt Method 4030 for use in their Underground Storage Tank (UST) Programs, e.g. Georgia and California.

6.3 Examples of Performance Based Measurement Systems

The USEPA has established a policy that, where possible, the Agency will use the PBMSs approach in its monitoring programs for generating environmental data.[83] The Agency defines PBMS as a set of processes wherein the data quality needs, mandates or limitations of a program or project are specified, and serve as criteria for selecting appropriate methods to meet those needs in a cost-effective manner.[94]

The PBMS approach has been the basis of the RCRA monitoring program since its inception back in 1980. The inherent flexibility of this approach is an absolute necessity for a program that has responsibility for overseeing analyses in a wide variety of diverse media. The approach is very simple in nature. Rather than focusing on a prescriptive method approach, where following a published method exactly as written is the main requirement, the PBMS approach focuses on a series of questions to be answered about a specific application. These questions are based on the scientific method and focus on whether a selected method or methods can provide performance appropriate to address the data quality requirements of a particular project. The questions include:

1. What is the purpose of this analysis? (Why are we doing this analysis?)
2. How (for what action) are the data generated from this analysis to be used?
3. What are the data quality needs for this project, i.e. how good does the data have to be for it to be useful for its intended purpose? (Including regulatory drivers, target analytes, matrices, concentration levels, statistical confidence levels, etc.)

Immunoassay methods are the ultimate tools for demonstrating and using this PBMS approach. They are designed and manufactured around specific performance criteria, i.e. methods appropriate for use in Method 4020 are capable of determining whether a soil sample contains PCBs above a concentration of 5 ppm to a 95% upper confidence limit around the mean. There are currently four validated immunoassay products in Method 4020 that can meet these stated manufacturers' performance criteria, all of which utilize different chemistries.

6.4 Applications as Screening Methods

6.4.1 In the Field

OSW decided to take a cautious approach to the introduction of a new technology to the environmental field, with which most analytical practitioners were unfamiliar, and limit the initial applications of immunoassay methods to quantitative screening. We were aware that the technique had been used in Clinical Laboratories for many years in both screening and determinative applications. Since Regulatory Agencies tend to be slow to accept new and different approaches to analysis, anyway, we decided to take a ''walk before you run'' approach to introducing the new methodology to the people actually doing site assessments and cleanups.

The two primary applications of immunoassay methods in the RCRA Program are mapping of contamination at well-characterized sites slated for cleanup and monitoring the effectiveness of the cleanup activities. Immunoassay lends itself very well to these two particular applications. It is not particularly applicable to the identification and characterization of unknown contaminants at waste sites when compared to much more comprehensive techniques such as GC/MS. However, the reporter gene method (Method 4425) for planar aromatic compounds can be

used to determine the presence of and approximate concentrations of PAHs and chlorinated planar organics and distinguish between them. For monitoring applications of known contaminants, the specificity, sensitivity, and cost effectiveness of quantitative screening immunoassay methods are excellent.

Over the past few years, the general acceptability and willingness to use immunoassay methods within the USEPA Regions for RCRA and Superfund applications has increased exponentially. A significant factor in this change of attitude, in addition to OSW's attempts to educate users in the applicability of the technique, is the specter of shrinking budgets. Field people who are charged with actually doing cleanups are looking for more cost effective ways to do their jobs with less available money. A technique, such as immunoassay methodology, which can generate results of known quality in real-time, and can keep the bulldozers rolling can contribute significantly to reducing the costs of cleanups, and is being looked upon more favorably.

The initial application of immunoassay technology in the RCRA Program was for determining compliance at wood surface treating facilities with PCP regulatory limits. The selectivity and sensitivity of the immunoassay method easily met the regulatory action limit of 0.1 ppm. Use of the PCP immunoassay method (Method 4010) for compliance monitoring was encouraged by OSW and the method was added to SW-846 as a part of the Wood Surface Treatment Rule in 1994.

The major applications for which immunoassay methods are currently used in the RCRA Program are site mapping and monitoring cleanups at sites contaminated with PCBs. Use of the PCB method (Method 4020) has resulted in cost savings at many sites in several Regions. The speed and low cost of the test allows for more extensive mapping of contamination at a site, because many more samples can be analyzed on-site, thus generating a more detailed map of the site. This results in lower cleanup costs, since the cleanup efforts can be directed only at the places that need to be cleaned up, instead of to a broader area. The design of the method allows for rapid determination of whether or not the site cleanup level has been met, thus reducing costs of cleanup in both time and equipment. With the availability of the PAH method (Method 4035) and several types of kits with various sensitivities, the technique is now beginning to be used to monitor sites contaminated with PAHs.

Another major application within OSWER is for mapping and cleanup of sites contaminated with petroleum hydrocarbons from leaking storage tanks partially for the Office of Underground Storage Tanks (OUST) and primarily for the States. The TPH method (Method 4030) is effective for determining gasoline, diesel, kerosene, and jet fuel at most State-required cleanup levels.

The recent Department of Defense cutbacks set into motion a large number of military base closures in the United States, resulting in a plethora of site cleanup projects. The primary analytes of concern for these base closure cleanups were explosives, petroleum hydrocarbons and PCBs, all of which could be monitored using immunoassays and other screening techniques. The immunoassay ELISA methods for TNT (Method 4050) and RDX (Method 4051) have been used extensively along with the immunosensor methods (Methods 4655 and 4656) and the colorimetric screening Methods 8010 (for RDX) and 8015 (for TNT).

The ELISA method for mercury (Method 4500) has been used effectively to monitor the progress of the soil cleanups of several Superfund sites contaminated with mercury.

6.4.2 In the Laboratory

Immunoassay methods have been used in many laboratories to screen samples for high levels of contaminants to prevent instrument downtime. The dioxin screening method (Method 4025) was primarily designed for use in a laboratory, rather than in the field, because of the detailed sample preparation procedures involved. An effective dioxin screening method can result in significant cost savings for monitoring dioxin-contaminated sites. A negative immunoassay screening result can eliminate the need for a high resolution GC/MS analysis costing between $1500 and $2000 each. The method has been validated on a set of 56 real world soil samples and gave results that were 91% correct with 9% false positives. No false negatives were reported. It has also been used to screen river sediment samples and food samples potentially contaminated with dioxin.

6.5 Applications as Quantitative Methods

At the time of writing, there are very few quantitative applications for immunoassay methods. There are a few being developed. USEPA's Drinking Water Program is planning to incorporate Method 4670 for triazines as atrazine into its screening regulations. Current regulations require that drinking water suppliers test their supplies quarterly for atrazine at an MCL of 3 ppb. Method 4670 is appropriate for this measurement requirement, because it can measure these compounds sufficiently below the 3 ppb MCL to be effective. Since it also has a positive crossreactivity to other triazines, e.g. simizine and the like, the data generated as atrazine would be an overestimation and thus would be a conservative measurement.

Some of the more selective screening methods, e.g. TNT, RDX, and 2,4-D were originally submitted as screening methods for reasons described previously.

However, they are sufficiently selective to allow their use as quantitative methods. The TNT methods have been used for some quantitative applications on military base cleanups. They tend to generate high results with respect to TNT, because they also exhibit significant (and desirable) crossreactivity to TNT breakdown products such as DNT and DNB.

7 FUTURE DIRECTIONS

The environmental immunoassay method program has come a very long way, from nonexistent in early 1992 to a significant and viable program with a variety of available methods utilizing several different immunoassay technologies today. However, we still intend to continue to push ahead and keep the new methods coming and remain current with the state-of-the-art.

The primary focus right now is on completing the validations of the dioxins and coplanar PCB methods in Table 3, which is expected to be done by early 2000. We are also interested in continuing with the development of additional quantitative immunoassay methods for specific target analytes. We are continuing to investigate the applicability of immunoassay in the area of affinity chromatography.

Another area of interest for continued development is that of immunosensors. Several Federal Agencies are interested in further developing this technology beyond the realm of explosives. We are in the process of planning some preliminary projects, beginning in 2000, to complete the development of new immunosensors for PAHs, PCBs, and TCE.

Now that the industry has sorted itself out after the mergers of 1997, there are a number of small, energetic companies with a broad base of expertise in a wide variety of immunoassay techniques. We, in OSW, plan on continuing our productive relationship with these industrial partners to bring the best of immunoassay technology to bear on future environmental problems.

ACKNOWLEDGMENTS

The author would like to acknowledge Gail Hansen of the OSW Methods Team for her help in proofreading the manuscript and to several contributors of technical documents that helped him a great deal by providing him with the information that he needed to finish certain sections of this chapter. These contributors include Bob Harrison of Cape Technologies, Randy Allen of Hybrizyme, Jack Anderson of Columbia Analytical Services, and the other developers of immunoassay methods with whom I have worked over the years, particularly Steve Friedman of Sylvanus Laboratories, who has been my primary mentor in immunoassay technology over the years.

The first sections of this article describe a brief history, the basic principles and advantages as well as disadvantages of inductively coupled plasma mass spectrometry (ICPMS) over other analytical techniques commonly used for environmental analysis (see Figure 1). Section 4 is devoted to the discussion of the relative merits and demerits of a wide variety of dissolution techniques and their limitation in the pretreatment of various environmental samples. In section 5, efforts are concentrated on the novel application of ICPMS to such typical environmental samples as water, soil, and biological materials. In the last sections of the article, future perspectives of new ICPMS and related devices are discussed. The topics chosen are high resolution ICPMS, multiple-collector instruments, time-of-flight (TOF) ICPMS, collision cell interface ICPMS, and low-sample consumption nebulizers.

1 INTRODUCTION

In recent years, there has been ever increasing concern about the concentration levels of various trace and ultra-trace elements in environmental samples. In spite of this growing interest, the efforts of most environmental scientists appeared to be centered around limited numbers of typical pollutants. Phenomena occurring in the ''real world'' are for the most part so complicated that usually no clear cut conclusions can be reached when research work is limited only to the element in question. But because elements within the same Group and/or sub-Group of the periodic table possess similar chemical as well as physical properties, it can be expected that more comprehensive understanding will be obtained when all the elements are studied comparatively in relation to their position in the periodic table. In addition to this, various kinds of elements, which were not commonly used in the past, are now increasingly consumed by modern industries in the production of numerous new materials. There is a strong possibility that these industrial products will be disposed of in the environment and, hence will cause new types of environmental pollution. In order to cope with this situation, it seems essential to employ analytical techniques that possess rapid simultaneous multielement capabilities like ICPMS.

2 HISTORY

ICPMS is a relatively new technique that combines two well-established analytical tools (inductively coupled plasma (ICP) and mass spectrometry (MS)) to produce an instrument with powerful potential in the field of multielement trace analysis. ICP is used as a source of ions rather than as a source for optical emission measurement (as in inductively coupled plasma atomic emission spectrometry, ICPAES). Since the introduction of the first commercial ICPMS instruments in 1983, the technique has gained increasing attention from analytical chemists,[1,2] and the total number of instruments installed worldwide by the end of 1998 was estimated to be about 3000.

The major advantages of ICPMS over other analytical methods are:

1. increased sensitivity and wide dynamic range

Figure 1 Comparison of techniques used for environmental analysis (see text for abbreviations).

2. high selectivity
3. rapid multielement capability
4. simplicity in the spectra
5. low and uniform background
6. the ability to measure specific isotopes.

It should be noted, however, that there are also several disadvantages. These are as follows:

1. lower precision compared with ICPAES and atomic absorption spectrometry (AAS)
2. the total dissolved salts should be less than 1000 ppm
3. severe matrix effects
4. higher cost of the instrument.

3 INSTRUMENTATION

3.1 Instrument Overview

A schematic representation of the main components of a typical ICPMS instrument is shown in Figure 2. Although ICPs are basically similar to those that have been used in emission spectrometry (ICPAES) for many years, the torch is mounted horizontally rather than vertically (torches have also been mounted horizontally in ICPAES). The interface between the plasma and the mass spectrometer consists of two cones: the first is called the sampling cone and the other one that is installed behind the sampling cone is known as the skimmer cone.

Transfer from the skimmer to the mass analyzer is effected by a system of electrostatic lenses, which extract the positively charged ions and focus the ion beam in a form suitable for transmission through the quadrupole mass filter. The mass filter transmits the ions of a particular selected mass to charge ratio (m/z) to an ion detector (channel electron multiplier) that registers the ions. Each

Figure 2 Schematic diagram of a typical ICPMS instrument. (Modified from the original drawing provided by Yokogawa Analytical Systems, Japan.)

naturally occurring element has a unique and simple pattern of near-integer mass to charge ratio corresponding to its stable isotopes. Accordingly, the identification of an element is very simple and straightforward. The number of registered ions from a given isotope depends, of course, on the concentration of the relevant elements in the sample. More detailed descriptions of the instrumentation of ICPMS have been presented elsewhere.[3–5]

3.2 Inductively Coupled Plasma

The ICP is produced by passing ionized Ar gas ''seeded'' with a few electrons from a Tesla Coil through a quartz torch located inside a Cu coil that is connected to a radiofrequency (RF) generator. The high-frequency currents from the generator flow in the Cu coil and thus generate oscillating magnetic fields. Electrons and ions passing through the oscillating electromagnetic field flow at high-acceleration rates in a closed annular path inside the quartz tube. The direction and strength of the induced magnetic fields varies with time, resulting in electron acceleration at each half cycle. Collisions between accelerated electrons (and ions) and unionized Ar gas cause further ionization. However, other Ar atoms impede the movement of this current of charged particles and cause ohmic heating of the gas.

3.3 Sample Introduction Systems

A key advantage of ICPMS over other types of MS is that the ion source (ICP) is located outside the vacuum system and allows much simpler sample introduction.

For analysis by the ICPMS technique, samples must be in a form which can be carried in a stream of Ar gas (nebulizer gas). The most convenient method for sample introduction into the gas stream is the generation of a fine aerosol using a nebulizer and a spray chamber, as illustrated in Figure 2, because most of analyses are carried out on liquid samples.

3.3.1 Pneumatic Nebulization

The basic principle of pneumatic nebulization is that the stream of sample solution is disrupted by a high velocity gas flow to produce a spray of droplets. The construction of a pneumatic nebulizer suitable for ICPMS demands much greater skill because of the low gas flow rates. A spray chamber is attached to the nebulizer to remove most of larger droplets and to ensure that only the smallest solution droplets (less than 10-μm diameter) are carried into the plasma to avoid excessive cooling of the plasma. There are essentially three types of pneumatic nebulizer commercially available for ICPMS: concentric flow, crossflow, and Babington-type nebulizers. For those interested in more detailed information on this subject, reviews by Sharp[6,7] can be recommended.

The most widely used nebulizer is the Meinhard concentric glass nebulizer,[8] shown in Figure 3. This all-glass device is constructed by standard glassblowing techniques. Nebulizer gas (Ar) at a flow rate of around $1\,L\,min^{-1}$ is passed through the outer glass tube. The pressure drop generated (Venturi effect) causes the sample solution to be drawn up into the axial capillary and simultaneously discharged into aerosol droplets. The fragility and fineness of the sample inlet capillary and of the annular gas orifice are major drawbacks of this type of nebulizer. Blockage caused by the accumulation of salt particles (salting-up) and/or suspended solids is common, although a high salt tolerant type is also available.

The operation of the crossflow nebulizer is based on the well-known ''scent-spray'' principle.[9] A horizontal jet of gas passes across the top of a vertical tube. The reduced pressure so generated sucks the sample solution up the vertical tube, and at the top is dispersed into fine droplets (Figure 4). Although the analytical performance offered by the crossflow nebulizer is similar to the concentric type, it can be constructed from various materials other than glass. It is possible, therefore, to introduce solutions containing high concentrations of HF.

In the Babington-type nebulizer (Figure 5), the sample solution flows freely over an open slot or V-groove.[10,11] Gas forced through a small aperture in the bottom of the groove ruptures the fed solution to produce an aerosol. As the solution is simply flowing over a slot, rather than passing through a fine capillary, this type of nebulizer shows high tolerance towards samples with large amounts of dissolved solid, and even to slurries.[12,13]

Figure 3 Meinhard concentric glass nebulizer. (Reproduced with permission from J.E. Meinhard Associates Inc., USA.)

3.3.2 Ultrasonic Nebulization

The pneumatic nebulizer has been commonly used for sample introduction into the ICP. However, transport efficiency is extremely low, owing to the very wide range of droplet sizes produced. Ultrasonic nebulization greatly increases the transport efficiency and hence results in better analytical sensitivity and/or detection limits.[14–16] A schematic diagram of the ultrasonic nebulizer (USN) used in the author's laboratory is shown in Figure 6. A peristaltic pump is used to deliver the sample solution to the oscillating surface of the quartz plate. Aerosols with smaller and more uniform particle sizes are produced and transported first to the heated tube, and then to the condenser by the nebulizer Ar gas. Most of the water in the aerosol is removed by this process and only the dry aerosol is introduced into the plasma. The temperature of the heated tube is around 120 °C (slightly higher than the boiling point of water) and that of the condenser is usually set around 1 °C (near freezing point), and the sample introduction rate is typically $2–4\,mL\,min^{-1}$. CETAC Technologies has introduced a membrane desolvator to couple with the USN. The aim was to preserve the high

Figure 4 Schematic diagram of the crossflow nebulizer. (Modified from the original drawing provided by Nippon Jarrell-Ash, Japan.)

Figure 5 Simplified diagram of Babington-type nebulizer. (Modified from the original drawing provided by Perkin-Elmer, Japan.)

efficiency of USN and significantly reduce solvent loading into ICP.

3.3.3 Direct Injection Nebulizer

In the direct injection nebulizer (DIN), the aerosol is also generated upon the interaction of a high-velocity gas stream with the sample liquid as in many other pneumatic nebulizers. However, this newly developed nebulizer is unique in that the sample is delivered through a narrow thin-walled highly inert capillary tube by a high-pressure gas-displacement pump ($>40\,\mathrm{kg\,cm^{-2}}$). Argon gas passes into the nebulizer tip through the narrow annular space between the sample capillary and the nebulizer tip, where a fine mist with a narrow particle size distribution is

Figure 6 Schematic diagram of a USN.

created by the interaction between the nebulizer gas and the liquid sample. The absence of large droplets eliminates the need for a spray chamber and thus the analyte is directly injected into the central channel of the ICP. The DIN is an ideal sample introduction system for samples with limited volume, as the typical consumption of the sample is only $50–100\,\mu\mathrm{L\,min^{-1}}$. In addition, analysis of samples for elements with a greater memory effect, such as Hg and B, can be successfully carried out by DIN because the spray chamber is eliminated and the internal volume of the nebulizer is only a few microliters.

3.3.4 Chemical Vapor Generation

Several elements belong to groups IVB, VB, and VIB in the periodic table, namely Ge, As, Sn, Pb, Se, Sb, Bi, and Te form hydrides, which are gaseous at room temperature. These can be generated easily from aqueous solutions in a reducing environment. The most commonly used method for hydride generation is the acid–borohydride reaction. The capability of this technique has been fully exploited in AAS, and the AAS–hydride method is now widely used on routine basis.[17,18] Although less complicated batch processes are possible for hydride generation, continuous methods are generally preferred in ICPMS. This is because signals of shorter duration (transient response) are not suitable for multielement determination in ICPMS.

A schematic diagram of a continuous hydride generator is shown in Figure 7. The acidified sample solution and the reducing agent ($NaBH_4$ solution) streams are pumped through narrow-bore tubing by a peristaltic pump, and combine at a capillary T-junction, where a vigorous reaction begins. The solution passes into the phase

Figure 7 Schematic diagram of the hydride generation system. (Modified from the original drawing provided by Yanagimoto Mfg., Kyoto, Japan.)

separator and the gaseous products alone are carried to the plasma by the nebulizer gas (Ar).

3.3.5 Electrothermal Vaporization

Electrothermal vaporization (ETV), also developed in AAS (typically known as GFAAS, graphite furnace atomic absorption spectrometry), has come into widespread use for the determination of ultratrace levels of elements with considerable success.[19,20] The technique involves evaporation of a liquid sample directly into the plasma from an electrically heated graphite cuvette. Whereas the full atomization of the sample solution in the cuvette is the major concern in AAS, the evaporated samples could be further transported effectively (nebulizer and spray chamber are removed) into the plasma in ICPMS. Therefore, the ETV device for ICPMS and/or ICPAES[21,22] is (Figure 8) considerably different from that used in AAS.[19,20]

The major advantage of ETV is the very much improved sample introduction efficiency compared with the pneumatic nebulizer. The improvement in sensitivity is, therefore, an order of magnitude or more. In addition, the level of oxide ions is dramatically decreased because only the dry aerosol is introduced into the plasma. For example, considerable reduction in detection limit for ^{56}Fe results from reduced spectral overlap from ^{40}ArO.

3.3.6 Laser Ablation

In this technique, a laser is used as a method of volatilizing sample materials. The system is illustrated schematically in Figure 9.[23] The sample is located in a quartz or glass cell of small volume, typically 30–100 mL, to minimize dilution of the sample vapor. The laser beam passes through the optical window and vaporizes a small part of the sample. The vapor ablated from the sample surface is then transported directly to ICP by the carrier (nebulizer) gas. When the ablated material reaches the ICP, a pulsed signal of short duration is observed similar to the peak obtained using ETV. This method allows direct analysis of the solid sample with minimum preparation. In addition, microprobe analysis can be developed when laser ablation is used with a device that controls an X-Y motion of the sample.[24]

Figure 8 Schematic diagram of ETV for ICPMS. (Modified from the original drawing provided by Yokogawa Analytical Systems, Japan.)

Figure 9 General arrangement of laser, ablation cell, and gas flow.

3.3.7 Other Techniques

One of the unique features of the ICP is its ability to accept a wide range of sample introduction systems. Modifications of ICPMS are, therefore, relatively simple and hence, hyphenated systems for specific purposes will be easily constructed. Introduction systems with greater potential are liquid chromatography (LC), and flow injection (FI).

The former (LC/ICPMS) provides information about the chemical forms, or elemental species, rather than about total amount of elements alone. In addition, on-line separation from the matrix elements and/or preconcentration are easily attainable when combined with appropriate LC systems. FI/ICPMS systems are advantageous for solutions with high dissolved salts content because only a limited amount of sample, usually 50–100 μL, is injected into a continuously flowing stream of a carrier solution of very low or no salts content.

4 SAMPLE PREPARATION

4.1 Methods of Dissolution

For the total analysis of solid samples, all the elements have to be brought into solution, although such techniques as laser ablation[23,24] and slurry introduction[12,13] are known to be available. Classical thermal decomposition methods (dry ashing) are not applicable for ICPMS because loss of certain volatile elements and/or contamination during the ashing procedures are rather common in these methods. As solutions of high salts content are not suitable for ICPMS, fusion methods are also not acceptable unless the analytes are subsequently separated by applying appropriate chemical techniques. A further problem associated with this method is the difficulty of obtaining high-purity fusion reagents (fluxes), such as $NaCO_3$ and $Na_2B_4O_7$. As a consequence, digestion with strong acids (wet digestion) is exclusively used in ICPMS, although the fusion techniques are often required to dissolve the refractory substances mentioned below. Acids of ultrahigh purity are commercially available now.

4.1.1 Open Digestion Systems

Digestion methods for plant and tissues and related materials for ICPMS are essentially similar to those already developed for other types of analytical methods, especially for ICPAES and AAS. Typically, 0.5–1 g of finely ground samples are treated with HNO_3–$HClO_4$

on a hot plate, followed by dissolution of the residue and dilution to 50–100 mL. The use of H_2SO_4 is not recommended because of the adverse effects of this acid in the subsequent ICPMS measurements.

The use of HF, in combination with $HClO_4$ and HNO_3, is a well-established method for the dissolution of samples to determine the total element content of silicate minerals and related materials, and has been extensively applied in AAS and ICPAES.[25–27] Although Si is lost by evaporation of gaseous SiF_4 when an open system is used, no problem will arise because ICPMS is mostly applied to trace and ultratrace analysis. A problem can arise, however, because some minerals, such as chromite ($FeCr_2O_4$), garnet ($R''_3\ R'''_2(SiO_4)_3$, where R″ may be Ca, Mg, Fe, and Mn, and R‴ may be Al, Fe, Cr and Mn), magnetite (Fe_3O_4), and zircon ($ZrSiO_4$), resist acid attack and remain undissolved even after repeated treatment. As these minerals almost always contain a wide variety of elements as ''impurities'' (a typical example is Hf and heavy rare earth elements in zircon), special dissolution techniques should be applied for samples containing considerable amounts of these minerals. Care is also required when the $HClO_4$–HF mixture is evaporated to dryness, because acid insoluble oxides will be formed again if too much heat is applied.

The advantages of the open digestion systems are as follows:

1. Silicon and the excess HF are easily removed by heating.
2. The final solutions are stable (silica-bearing solutions tend to hydrolyze and precipitate on standing).
3. The removal of corrosive HF allows the solution to be handled in conventional glassware for periods of at least a couple of days.
4. The salts content of the resultant solutions is low.

4.1.2 Closed Digestion Systems

An alternative dissolution procedure using HF is to digest the samples in a sealed Teflon vessel or ''Teflon bomb'' placed in a stainless steel casing.[28–30] Bombs with different designs are now commercially available (Figure 10). After the addition of sample and acid, the bomb is sealed and heated in an electric oven.

The advantages of closed digestion systems over the open vessel techniques are as follows:

1. Digestion at higher temperatures is possible because the boiling point of the reagents is raised by the pressure generated in the vessel. This may shorten the time needed for decomposition and also enable the dissolution of some acid-tolerant minerals.

Figure 10 Diagrammatic cross-section of a ''bomb''. (Modified from the original drawing provided by Yanagimoto Mfg., Kyoto, Japan.)

2. Volatile elements, such as B, Cr, As, Se, Sn and Hg, will remain within the vessel.
3. Smaller amounts of acid are sufficient for the digestion because evaporation does not occur. This lowers the reagent blank level considerably.
4. Contamination is significantly reduced because the sealed system prevents the introduction of airborne particles during decomposition.

The disadvantages are the following:

1. The maximum amount of sample that can be processed is rather limited, usually less than 0.5 g. This is especially the case when the content of organic matter in the sample is high.
2. Large amounts of H_3BO_3 should be added to complex the excess HF. This results in high salts content in the analyzing solutions.
3. Subsequent open vessel procedures are needed when the removal of Si and HF is required.

Heating needed for the acid decomposition of samples is traditionally provided externally via chemical flames or electrically on hot plates. However, methods using microwave energy for heating have been

widely accepted.[31] This technique is applied most suitably to closed digestion systems because the sample solutions can be heated directly in microwave ''transparent'' vessels. Although domestic microwave ovens can be used successfully, purpose-built microwave digestion systems are commercially available. Very rapid heating is possible in comparison with open digestion and bomb methods because the heat is generated from inside rather than supplied from outside. A comprehensive review on this subject has been published.[32]

5 ENVIRONMENTAL APPLICATIONS

5.1 Overview

The definition of environmental analysis seems to be not very clear. But when samples are analyzed in connection with problems associated with environmental deterioration, these activities are usually termed ''environmental analysis''. Therefore, the sample types considered in this section cover various different materials with diversely different natures, such as water, soils and sediments, biological samples including foods and animal tissue, and geochemical samples. Literature retrieval has shown that more than 150 reports related to environmental analysis by ICPMS were published between 1996 and 1998. The types of sample examined in the literature and their relative ratios (%) are shown in Table 1.

Extensive annual reviews of environmental analysis have been published from 1985 by the Royal Society of Chemistry (UK) in the *Journal of Analytical Atomic Spectrometry*. In addition to these, there also have been a large number of reviews on specific types of samples and topics, as well as reviews on environmental analysis in general published in several different languages. These are soil samples,[34] double-focusing sector field ICPMS,[35–37] sediment, river water and seawater (in Japanese[38,39]), trace radioactivity,[40] boron in plants and soil,[41] trace element species,[42] speciation by gas chromatography (GC) ICPMS (Japanese,[43] Chinese[44]), speciation by LC/ICPMS,[45] speciation by HPLC ICPMS,[46] speciation by capillary electrophoresis ICPMS (Chinese[47]),[48] ETV/ICPMS (German[49]), isotope ratio analysis of environmental and biological samples (Japanese[50]), Pu in environment[51] and environmental samples in general[52–55] (Japanese[56,57,83,105]).

Therefore, it is not the author's intention to prepare a comprehensive review in this article but rather try to introduce several resent research works as examples.

Table 1 Applications of ICPMS to water analysis

Sample, techniques and elements	Ref.
Volatile metal(loid), GC/ICPMS	97
River water, comparison with neutron activation analysis	98
Rainwater, heavy metals	99
Rainwater, Pb isotope ratios	100
Seawater and sediment, Pb isotope ratios	101
As and Se, HPLC/ICPMS	102
Tap water and river water, ^{99}Tc	103
Seawater, flow injection, Pb, Cd	104

Rain and dry fallout, ^{99}Tc	110
Coastal seawater, ^{99}Tc	111

HPLC, high-performance liquid chromatography.

5.2 Detection Limits and Range

The periodic table in Figure 11 shows 70 or so elements that can be determined by ICPMS and their approximate detection limits. In ICPMS, detection limits are defined as the analyte concentration equivalent to three times the standard deviation (3d) of the blank response (background) measured, in most cases, in a single ion monitoring mode for an integration time of 10 s. The standard deviation of the blank solution is calculated from 10 consecutive measurements carried out within a relatively short period (usually less than 10 min). It should be noted, however, that 5–10 times the detection limits are usually required for good qualitative measurements.

Figure 11 Periodic table showing the detectable elements and their approximate detection limits. Unhatched elements have not been examined yet.

The detection limits for a considerable number of elements are about 1 part per trillion (ppt). The elements not suitable for ICPMS measurements are the halides, the inert gases and atmospheric gases. Elements with a low sensitivity and/or higher detection limits fall within these groups. The so-called nonmetallic elements are not easily converted to positively charged ions.[33] The higher detection limits observed for Si, K, Ca, and Fe are mainly due to the higher background signals caused by spectral overlaps of various molecular species originating from the matrix and/or gaseous components in the plasma (e.g. Ar, N, H and O).

5.3 Water Analysis

The types of water samples in environmental studies include lake water, river water, seawater, groundwater, and rainwater. However, assessment of water quality often necessitates analysis of related samples such as sediments, suspended materials, and aquatic biota, including algae, higher aquatic plants, insects and fish. For such samples, analytical procedures are essentially similar to those for soils and biological samples described below. Suspended materials are removed by filtration through a 0.4–0.45-μm pore size membrane filter or centrifugation.

The detection limits of ICPMS are, in general, low enough to allow the analysis of natural water samples without using preconcentration procedures.[58–73] If separation and/or preconcentration steps are needed to reduce or eliminate matrix interferences (for example, seawater), wide varieties of techniques including ion exchange,[74–78] coprecipitation,[79] solvent extraction,[80–82] solid-phase extraction,[83] and chromatographic resin[84] are available.

Miyazaki and Reimer[85] determined Pb concentrations and isotope ratios after preconcentration with a Chelex-100. A similar FI procedure has been applied to the analysis of concentrated brines[86] and seawater.[87] Seubert et al.[88] described synthesis of an inert type of 8-hydroxyquinoline-based chelating ion exchanger to be used for seawater analysis. It was possible to determine several elements in seawater in the low-ppt range by on-line ICPMS detection. An FI hydride generation technique has been described for the determination of As, Bi, Sb, Se, Te, and Hg in water at ultratrace concentration levels.[89–91] McLaren et al.[92] described an on-line method for the determination of trace elements in seawater. Shabani and Masuda,[93] and Aggarwal et al.[94] developed on-line methods for trace rhenium and sub-ppt levels of rare earth elements in seawater, respectively. Speciation of arsenic compounds in drinking water by capillary electrophoresis and hydride generation ICPMS has been reported by Magnuson et al.[95] It was possible to speciate four environmentally significant toxic forms of As: arsenic, arsenate, monomethylarsonic acid, and dimethylarsinic acid. Ion chromatography ICPMS utilizing hydride generation with a membrane separator was also investigated by the same authors for this purpose.[96] Interesting examples other than those described above are summarized in Table 1.

5.4 Soils and Related Materials

The first report on ICPMS appeared in 1980.[112] Although the total number of publications on ICPMS reached more than 3500 by April 1999, rather fewer applications of ICPMS for the analysis of soil samples and related materials have been reported.[113–134] These are summarized in Table 2. The high cost of the instrument appears to be the major reason preventing its widespread use among soil scientists. The price however continues to fall dramatically with increased annual production, so it might be expected that ICPMS will become one of the most widely used techniques for the determination of trace and ultratrace element concentrations, as well as for isotope ratio measurements in soil samples in the near future.

Yamasaki et al.[134] selected about 100 soil samples in such a way as to cover a wide range of chemical as

Table 2 Applications of ICPMS to soil analysis

Samples, techniques and elements	Ref.
Microwave-assisted leaching (EPA 3051)	113
Pt, road dust and soil	114

Figure 12 Periodic table showing the elements detectable in soil samples. The identified percentages for Groups 1, 2, 3, and 4 are respectively 100%, more than 90%, more than 70%, and less than 50%.

well as mineralogical compositions and examined the detectability of elements. A large number of elements were found (levels 10 times greater than the blank) in most soil samples. These elements are conveniently classified into four Groups, as shown in Figure 12 using the periodic table.

The elements classified in Group 1 were identified for all the samples examined. The problem associated with determination of these elements (except for Cu and Zn) is that high and variable dilution ratios (100–1000 fold) must be employed to adjust the concentration of each element to the optimum range. This not only requires time-consuming manipulation but also greatly reduces the multielement capability of ICPMS.

The elements belonging to Group 2 were detected in more than 90% of the samples. The unparalleled detection power of ICPMS is clearly demonstrated by the fact that it was possible to confirm the occurrence of more than 40 elements (Group 1 + Group 2) within several minutes. In addition to these elements, those classified in Group 3 were also found in about 70% of the samples. The elements in Group 4 were detected in only less than 50% of the samples. This indicates that the contents of these elements in soil samples are generally too low ($<0.1\,mg\,kg^{-1}$) for detection even with extremely sensitive ICPMS. It is apparent, therefore, that there are still a considerable number of elements for which we need adequate preconcentration and/or separation techniques to obtain reliable data on their content in soils.

5.5 Biological Samples

ICPMS is increasingly used for the analysis of biological samples mainly because of its high sensitivity, high selectivity and rapid multielement capability along with the ability to perform isotopic ratio measurements. Sample preparation procedures for ICPMS measurements are essentially similar to those for other types of environmental samples, although the use of HF is seldom needed for biological samples. Although the amount of the decomposable sample is usually limited to less than 1.0 g, microwave digestion (see section 4.1.2) is most suitable because samples can be decomposed using only HNO_3 by this technique.[135] This makes it possible to eliminate the use of $HClO_4$ and/or H_2SO_4 which are known to produce various molecular species which overlap with many important isotopes.[136] Table 3 shows some recent applications of ICPMS to biological samples. Reviews by Barnes[160] and Mukai and Yoshinaga[161] can be used for more detailed information.

6 METHOD DEVELOPMENT

6.1 High-resolution Inductively Coupled Plasma Mass Spectrometry

6.1.1 Background of Development

Although ICPMS has various advantages over other analytical techniques as mentioned previously, it has become evident that high selectivity and simplicity of spectra are not always the case. This is mainly because

various polyatomic molecular species, originating from gaseous components (i.e. H, C, N, O, and Ar), matrix elements in samples, and components in acids or alkalis used for sample dissolution are formed in spite of the high temperature of the plasma. It is often the case that spectra appear simple only because the commonly used quadrupole-type mass spectrometers in ICPMS are incapable of separating chemically different ions at the same nominal m/z value.

The driving force behind the development of a new type of high resolution instrument that uses a double-focusing mass spectrometer has been the separation of the analyte ions from the overlapping polyatomic ions which is especially noticeable in the region between mass 40–80, that is, from ^{40}Ar to $^{40}Ar_2$.[162,163] Typical examples of such overlapping peaks and the resolution needed for the separation of the analyte ions are shown in Table 4.

6.1.2 Instrumentation

Commercial high-resolution ICPMS was first launched by VG Elemental (now Micromass UK Ltd.) in 1988. Similar systems were also introduced into the marketplace by two other manufactures (JEOL in Japan and Finnigan MAT in Germany). In 1998, the total number of this type of instrument working in the whole world was estimated to be more than 200 provided by four manufacturers. A schematic representation of the main components of the ELEMENT, an instrument provided by Finnigan MAT, is shown in Figure 13.

The main reason for developing the high-resolution ICPMS was to resolve molecular overlaps caused by matrix species. However, it has also become evident that the detection limits of most elements are significantly improved when this instrument is operated in the low resolution mode because of the much lower background signal and higher ion transmission. The low background is because the long and curved ion flight path together with the complex focusing elements prevent photons from reaching the detector. The higher ion transmission is the result of ion acceleration and efficient focusing.

Table 4 Resolution required to separate interferences

(m/z)	Analyte	Interferent	Resolution
28	Si	$^{14}N_2$	960
32	S	$^{16}O_2$	1800
51	V	^{35}ClO	2600
52	Cr	$^{40}Ar^{12}C$	2400
55	Mn	ArNH	1600
56	Fe	ArO	3000
75	As	ArCl	7800
80	Se	Ar_2	9700

(Reproduced with permission from Finnigan MAT, Germany.)

6.1.3 Resolution and Sensitivity

Figure 14 illustrates how the signal intensity changes with resolution.[58] Data was obtained by aspirating the 1-ppb (parts per billion) indium (In) solution using a USN. Signal intensity is expressed in terms of counts per second (Hz) per parts per million (ppm) of In. The analyzing system used in this experiment has such excellent detection power that a signal intensity as high as 2 GHz ppm^{-1} is reached when the instrument operates in the lowest resolution mode (i.e. with both slits opened wide). The resolution in this mode is estimated to be around 400. When the resolution is increased to 1500 to separate, for example, Si from N_2, the sensitivity decreases to 60% of that obtained in the low-resolution mode. If the resolution is further increased to 3500 for the first transition elements, the signal intensity is around 400 MHz ppm^{-1}. At a resolution of 8500, the sensitivity is only 2% of that attained in the low-resolution mode.

6.1.4 Typical Detection Limits

Detection limits of a high-resolution instrument are summarized in Figure 15. These values were obtained under essentially similar conditions to those in quadrupole-type instruments, although sample solutions were introduced through a USN.[58]

As mentioned above, spectral overlaps caused by polyatomic molecular species originating from gaseous components and/or matrix elements are common in the mass range of 40–80, so measurement of the first transition elements must be carried out in the high-resolution mode. Because sensitivity decreases sharply

Figure 14 Sensitivity versus resolution curve. Data was obtained using 1 ppb of indium (In) solution. Signal intensity is expressed in terms of counts per second (Hz) per ppm of In.

Figure 15 Typical detection limits obtained by a high resolution ICPMS. The total peak dwell times (integration times) were 5 s. Reliable values were not obtained for those elements shown in italics (Na, K, and Ca) owing to higher blank levels. Other unhatched elements have not been examined yet.

when the instrument operates in the high resolution mode, as shown in Figure 14, the detection limits of these elements were expected to be considerably higher than those of the elements for which measurements can be done in the low-resolution mode. It can be seen, however, that the detection limits of the first transition elements, except Fe, are all well below 1 ppt even in the high-resolution mode. This high value for ^{56}Fe can be attributed to the higher total counts of the blank, presumably owing to the effect of $^{40}Ar^{16}O$. It was not possible to obtain reliable values for Na and Ca because of a very high blank value possibly originating in the sample introduction system and/or owing to the memory effects.

With the exception of Mg, Si, P, S, Ge and As, detection limits of elements other than the first transition elements were below 0.1 ppt, and reached as low as less than 1 ppq (0.001 ppt) for some elements.

Because the instrumental conditions for the measurement of each element are different, it seems impossible to relate the detection limits to the nature of the element based on comparison of these values between different elements. There is a general tendency, however, for the detection limits of monoisotopic elements to be lower than those of other elements because the signal intensities for each isotope are, in principle, proportional to its abundance. A much higher detection limit was observed for As because it must be measured in a very high-resolution mode because of $ArCl^+$, and the high value for Si is due to a high blank value possibly originating from the sample introduction glassware and/or a torch made from quartz. The disappointing detection limits for Ir and Pt appear to be due to higher blank signals presumably originating from the sample introduction tube made of Ir–Pt alloy. In contrast to this, the higher detection limits for P and S apparently resulted from a combination of the lower degree of ionization for these elements[4] and the requirement for a higher resolution (i.e. around 1000) mode to be used.

6.2 Multiple-collector Instruments

The precision of isotope ratio measurements attainable by ICPMS are much poorer than those by thermal ionization mass spectrometry (TIMS), which is widely used as the benchmark method for the very precise determination of isotope ratios in such fields as isotope geology and nuclear sciences. Apparently, this limited precision is a consequence of the unstable nature of ICP. Theoretically, considerable numbers of errors caused by the instability of the ion source can be eliminated if each isotope ion is measured simultaneously by using multiple-collector systems. This type of instrument was introduced into the marketplace by VG Elemental in 1994 (Figure 16). Precision of the order of 0.03–0.003% has been reported for these instruments.[164,165] At present, this type of instrument is provided by three different manufacturers

Figure 16 Schematic diagram of a double-focusing multicollector ICPMS, P54. (Reproduced with permission from VG Elemental, UK.)

and more than 40 sets of machines are working all over the world.[166]

The advantages of this instrument over TIMS are as follows:

1. Sample preparation procedures are simplified.
2. Measurement time is much shorter (several minutes) than TIMS (typically several hours).
3. Mass bias correction can be made using separate elements.
4. Precise ratios can be measured even for transient signals originating from such techniques as ETV and laser ablation.

Another type of multiple-collector instrument with the collision cell interface (see section 6.4) has been introduced into the marketplace by Micromass UK Ltd.

6.3 Time-of-flight Instruments

Myers et al.[167–169] described a novel type of ICPMS combined with a TOF mass spectrometer (ICP/TOF/MS). In the TOF instrument, separation of ions is based on the measurement of the TOF of ions of known energy over a known distance. As it is possible to measure the flight times of all the ions, TOF/MS is very efficient compared with other types of mass spectrometer, where only a very small fraction of the ions are measured in the collector system. Detection limits were from 0.4 to 2 ppb.[169] ICP/TOF/MS is currently provided by two manufacturers (GBC Scientific Equipment Inc. and LECO Corporation).

6.4 Collision Cell Interface Inductively Coupled Plasma Mass Spectrometry

The usefulness of collision cells to attenuate polyatomic ion interferences in ICPMS has been studied by Douglas,[170] Rowan and Houk[171] and Bricker et al.[172] A new type of quadrupole ICPMS equipped with a hexapole RF collision cell (Platform ICP) was launched by Micromass UK Ltd. The collision cell is placed between the skimmer cone and the quadrupole mass analyzer to reduce interference resulting from Ar-based molecular ions. The detection limits for easily ionizable elements such as Pb, In, Sr, were less than 1 ppt, and those for difficult elements including Fe, Ca, K, Cr, As and Se were around 10 ppt.[173] A similar type of instrument (Dynamic Reaction Cell) is also provided by Perlin Elmer/Sicex Corporation. However, further work on more difficult samples seems to be necessary before the usefulness of this very new technique can be evaluated fully.

6.5 Low Sample Consumption Nebulizers

Two types of nebulizer with much lower sample uptake rate have been introduced into the marketplace. One is a high-efficiency nebulizer (HEN) provided by J E Meinhard Associates,[174] and the other is a microconcentric nebulizer (MCN) (Figure 17) from CETAC Technologies.[175] The MCN comprises a nebulizer body with polyimide capillary and spray chamber end-cap adapter. The latter is used to connect the sample tubing to standard Scott-type spray chambers.

These kinds of devices including DIN (section 3.3.3), and several other prototypes not yet commercially available have clear analytical advantages for environmental samples. First, they will often be useful where the amounts of samples are limited, such as animal tissues and body fluids. Second, the reduction in sample amounts immediately results in the reduction of the analytical cost needed for sample collection and storage.

Figure 17 Schematic diagram of an MCN. (Modified from the original drawing provided by CETAC Technologies.)

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectrometry
DIN	Direct Injection Nebulizer
ETV	Electrothermal Vaporization
FI	Flow Injection
GC	Gas Chromatography
GFAAS	Graphite Furnace Atomic Absorption Spectrometry
HEN	High-efficiency Nebulizer
HPLC	High-performance Liquid Chromatography
ICP	Inductively Coupled Plasma
ICPAES	Inductively Coupled Plasma Atomic Emission Spectrometry
ICPMS	Inductively Coupled Plasma Mass Spectrometry
LC	Liquid Chromatography
MCN	Microconcentric Nebulizer
MS	Mass Spectrometry
RF	Radiofrequency
TIMS	Thermal Ionization Mass Spectrometry
TOF	Time-of-flight
USN	Ultrasonic Nebulizer

Industrial sites where residues and wastes such as slags, ashes, dust and sludges have been dumped are essential parts of the environment and of the economic structure. The amount of waste produced, distributed and deposited is constantly increasing. The wastes can contain hazardous components that pollute and endanger the environment, but they can also consist of valuable materials, which are a source of secondary raw materials. To assess the environmental risk caused by the waste, or to calculate the economic benefit of dumped material, a reliable knowledge of the waste composition is required. Waste management experience has regularly shown that conflicts and lawsuits are the result if the composition of the waste materials is difficult to determine reliably. Investigations carried out by different institutions and persons, or by the same personnel under varying conditions, will often have very different results. The measuring technology and the measuring methods cannot be the only reasons for that. Nowadays, it is possible to accurately determine chemical components in any natural concentration, and there is no problem in distinguishing the size and shape of particles down to the nanometer scale. The problems are created because the wastes are mixtures of particles and lumps which vary in size and shape as well as in chemical composition and physical properties. A waste dump with a varied production history and dumping conditions, with chemical reactions or physical changes occurring after dumping, will be heterogeneous as a rule. Therefore, the evaluation of any dump of industrial waste materials is quite difficult. To ensure that the results of evaluation are comparable, certain regulations of investigation must be followed. According to the delivery, the wastes are classified into material streams (stationary, moving or free falling), heaps delivered within containers and vehicles, and free-standing heaps. As it is economically unjustifiable to investigate the entire waste dump, subsets of material (called samples) must be taken from the stream, the container or the heap in order to determine the measurements of interest. In doing this, rather a lot of errors can be made. Therefore, the errors that exist are frequently caused by unobjective sampling and improper handling of the sample material. However, a false estimation can also be made by evaluating reliable data using unsuitable statistical methods.

The present contribution takes up this problem. An industrial waste dump and a contaminated site were chosen as examples, and proven sampling regulations were applied. The applicability of known statistical and geostatistical methods developed for homogeneous granular bulk solids and uniformly contaminated soils to the evaluation of extremely heterogeneous waste dumps and nonuniformly contaminated industrial sites is shown.

1 INTRODUCTION

The evaluation of heterogeneous granular and lumpy industrial wastes by sampling and statistical data analysis is still a problem worldwide. First of all the sample must be obtained objectively, and secondly the sample material must be properly stored and preserved.

Sampling is objective under the following conditions:

- the sampler (person taking the sample) knows what material is being presented;
- the sampler knows the aim of the investigation;
- the sampler acts strictly according to certain regulations to reach the aim of the investigation;
- the sampler justifies these regulations to himself and to the client, and considers that the method of sampling prescribes how to evaluate the results.

For homogeneous granular mixtures and mining goods such as powders, sand, gravel, salt, iron ore and solid fuels, these problems have been thoroughly investigated. There are detailed instructions for sampling, for common procedures between the sampler and the laboratory, and for agreement between contracting parties.[1–3] The

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

evaluation of the results depending on the sampling scheme is controlled by mathematical models.[4,5] The handling of instructions and methods is justified by national and international standards, the applications of which are obligatory within the framework of the respective economic and legal systems.[6,7] The regulations, mathematical models, instructions and standards for sampling are based on the assumption of a small grain size range and a uniform particle shape. The methods of data analysis are based on mathematical statistics and geostatistics. They suppose a homogeneous isotropic material with uniform variation of the characteristic under consideration.

In contrast, industrial wastes can be extremely heterogeneous with respect to their material composition and to the degree of mixing of the individual portions. The concentration of harmful substances or the content of valuable material can vary considerably depending on the origin of the waste. Waste can consist of particles and lumps, with extreme distributions of particle size and shape. Characterization of the size and shape of lumps is not yet regulated by specific measures and dimensions.[8] Within an individual lump, several components can be intermixed, melted, screwed, welded or stuck together. Recycled products, wastes and scraps can also contain lubricants, cooling agents, brake fluids and other substances which make the material sticky, lumpy and greasy.

Pollutants in contaminated sites and soils can occur in complicated, partly volatile compounds which demand a lot from the handling and analysis of the samples.[9,10] Plants and animals can also serve as indicators of pollution. They require specific goals for sampling and special equipment for trace analysis[11,12] as well as particular care in sample preparation[13,14] and sample pretreatment.[15]

As a consequence, the assumptions underlying the geostatistics are not always correctly fulfilled by industrial waste dumps. There are still no special regulations expressly valid for the sampling of heterogeneous waste materials, and no statistical models specifically evolved for the evaluation of data obtained from wastes. Further research work is necessary in this field.[16] Previously, recommendations and statistical methods which are satisfactory or promising for other solids systems that are structurally or materially similar to the respective waste dump have been used.[17]

In the present article, a slag heap from Saxony, Germany, is used as an example in the application of sampling regulations and of known statistical methods for homogeneous bulk solids to the evaluation of extremely heterogeneous coarse grained and lumpy solids systems. The article also deals with the problem of the composition of a material being changed by improper handling after sampling. Soil samples taken from a mercury-contaminated industrial site are used as an example. It is shown that the mercury content detected by analysis is systematically decreased by improper preservation of the samples. Frequently, soil pollution is influenced by the geogenic background; it varies significantly as the location within the site is changed and as the sampling depth is varied. The investigations are planned in order to quantify the systematic error of sample preservation and to simultaneously distinguish the sample value from the geogenic background. For this reason, a statistical approach is proposed.

2 BASIC PROBLEMS OF SAMPLING AND ANALYSIS OF INDUSTRIAL WASTES AND WASTE DUMPS

The aim of sampling and analysis is to obtain a representative evaluation of the waste material. In doing sampling and chemical or granulometric analysis, two opposing principles have to be brought into line. On the one hand, the sample should be as large as possible, but this is not economical or practical. As a compromise, a sample having at least a certain minimum mass is required. The minimum sample mass is established according to certain mathematical models or empirically founded rules. This quantity increases as the particle size increases and as the reliability, which is required to describe the composition of the entire waste material by sample, enlarges. On the other hand, the amount of material needed for chemical or granulometric analysis is very very low. To get a final sample for analysis, the composition of which substantially represents the properties of the original sample material, very expensive sample preparation procedures must be applied such as comminution, homogenization (by mixing or melting), and dividing and reducing of the material. With these procedures, some errors are unavoidable. But sample preparation is not the only source of errors which influence the results of the investigation. All procedures, from sample selection up to statistical data analysis, cause unavoidable errors. Their effects on the evaluation are estimated as follows.

1. *Sampling* is the selection of samples from the waste material. Error at this stage is caused by global and local variations of the waste material and can amount to up to 1000% of the true value.
2. *Sample pretreatment* includes all events which can occur as a result of the handling of the samples, from their selection until preparation for analysis, and which cause the original properties to be changed. Volatilization or adsorption of components are examples of processes by which the material is

changed; pretreatment errors can amount up to 100% of the true value.

3. *Sample preparation* includes the processes of comminution, homogenization, division and reduction of the original material to establish the final sample for analysis. The maximum error of sample preparation is between 100% and 300% of the true value.
4. *Instrumental measurement*; this error is vanishingly small compared with those from the preceeding steps, and amounts to a maximum of 2–20% of the true value.
5. *Data analysis* is applied to solve the scientific problem using all the data available. If an incorrect mathematical model is used for this purpose it can cause an error up to 50%.

A simplified scheme of the unavoidable errors caused by the different steps in the material evaluation is shown in Figure 1.

Consequently, false sampling and gross defects in handling the material may influence the results of the investigation more seriously than the instrumental measurements. Generally, the following principles are valid:

- if the sampling is false, everything is false;
- if the measured values are right, but the method of data evaluation is unsuited for the intended purpose, the results of the evaluation may be doubtful.

To limit the errors of evaluation, every step from sampling up to data analysis must be carried out strictly according to certain regulations and specific mathematical methods. To plan the investigation, the following questions are asked.

1. What is the special purpose of the investigation and what is already known about the waste dump or the industrial site?
2. What additional information is striven for?

To answer these questions, the following parameters are established:

1. The sampling design, which defines the time, the location and other conditions of sampling that are essential for the characterization of the waste material (dump, stream, site). When planning the sampling conditions, the sampler has to imagine an appropriate structure for the object of investigation.
2. The number of samples.
3. The minimum mass of an individual sample and the gross sample mass.
4. The sample handling procedures, which are necessary to ensure that the data are of the required quality.

Figure 1 Simplified scheme of the steps in the evaluation of material systems.

Handling includes all the procedures for transport, preservation, preparation, decomposition for chemical analysis, etc.

5. The quantity to be measured.
6. The methods of statistical data analysis. These methods have to be suitable for the sampling design.

The success of sampling and data analysis is measured by

- the accuracy (precision)
- the confidence (trustworthiness) and
- the reliability

of the waste characterization.

The gist of these criteria is explained as follows.

1. Accuracy or precision: Let μ be the true value of a characteristic of interest (e.g. the content of a hazardous component). This value is not known and can only be estimated from samples. An error $|\overline{Y}_n - \mu|$ is made by using the mean value $\overline{Y}_n$ obtained from n samples instead of the true value μ. This error is called the *accuracy of estimation* (accuracy of prediction) of μ by the mean $\overline{Y}_n$. In practice, an upper limit ε_0 of $|\overline{Y}_n - \mu|$ is prescribed. The limit ε_0 is termed the *maximum admissible error of the mean*.
2. Confidence: Because the accuracy of estimation $|\overline{Y}_n - \mu|$ is a random variable, a probability β must be given, where the relation $|\overline{Y}_n - \mu| \leq \varepsilon_0$ is valid. The value β is called the *confidence probability* of the admissible error of the mean. In practice, a β value between 0.90 and 0.99 is recommended.
3. Reliability: When using inaccurate data, a certain risk (e.g. expected loss of confidence, additional costs) must be taken into account. If the risk associated with a data set is acceptable, it is called a *reliable* data set.

In the following section, some experiences in sampling and sample pretreatment are presented.

3 SOME EXPERIENCES

3.1 Geostatistical and Statistical Evaluation of a Heterogeneous Industrial Site

3.1.1 Object Investigated

The slag heap of a smelting plant at Freiberg in Saxony, Germany, was investigated. Further studies have also been carried out.[14,18,19] Rasemann and Markert[14] have explained the methodical concept of investigation and the statistical methods used for evaluating the results of sampling and analysis. In this article some of the practical conclusions reached in the papers mentioned with the help of additional data have been proven to be true. The slag was a by-product from the thermal processing of zinc blende (ZnS) ore concentrates. The concentrates were roasted in a fluidized-bed roasting furnace which produced calcined zinc oxide and sulfur dioxide in the roaster gas. The roaster gas was used to produce sulfuric acid, which was used to leach the calcine. The leaching was followed by separation into solid low-grade leaching tailings and high-grade leachate. The leachate was an electrolyte, from which the zinc was cathodically precipitated. The leaching tailings consisted of the remaining portions of zinc and other valuable components such as lead, cadmium and iron. The tailings were washed and dried, and then thermally processed in a rotary furnace to extract the metals. Fine coke was added to reach a high furnace temperature and to reduce the metal oxides. The residue of this process, the rotary furnace slag, was continuously discharged, then cooled, granulated and transported to a slag pit. Finally, the slag was moved by truck from the pit to the dump.

The leaching tailings processed were delivered from different factories so they varied in composition over the entire operating period. Consequently, the rotary furnace slag was composed of widely varying portions of SiO_2 (10–20%), FeO (15–30%), CaO (10–15%), Al_2O_3 (about 6%), C (10–45%), S (about 6%), Zn (1–5%), Pb (0.1–2.5%) and Cu (0.3–0.6%). Cadmium and arsenic also occurred in low concentrations. The high carbon content resulted from unburnt coke. After the slag was dumped, the fine coke in the heap was carbonized at low temperatures, parts of the normally grained slags were incinerated, the heap caved in and the slags were sintered to blocks here and there. The very heterogeneous slag heap thus consisted of blocks and lumps of slag and of coarse-grained bulk material. The chemical composition was extremely varied. After the first inspection, the heap surface was distinguished by three regions (Figure 2):

- normally grained slag which was partly burnt
- very incinerated regions
- solid blocks and lumps of sintered slag.

The heap extended over an area of 1.6 ha and it was between 4 and 12 m high. The total mass was about 80 kt.

3.1.2 Sampling Strategy

3.1.2.1 Sampling Pattern, Number of Samples and Mass of an Individual Sample For evaluation, the area was covered by a regular grid consisting of 60 points

Figure 2 View at the rotary furnace slag heap of the smelting plant at Freiberg in Saxony.

forming equilateral triangles with sides of 10 m. The efficiency of such a grid is evaluated as follows.[20] If there is no information about the spatial distribution of contaminants or valuable components, the largest uninvestigated subsection of the grid may be a criterion for the probability of incorrect evaluation. To compare different grids, such a subsection is defined as the area of a circle drawn to connect adjacent grid points. A grid with minimal uninvestigated subsections compared with any other geometric pattern is assumed to be optimal. This condition is found to be fulfilled by a grid of equilateral triangles. A square and an equilateral triangle, as respective units of a regular grid, are compared with each other in Figure 3. The squared grid completely neglects a circular area of 157 m^2 and can only recognize circular contaminations exceeding a radius of 7.07 m with certainty. In contrast, only 104.7 m^2 remains unrecognizable, and circular contaminations having a minimum radius of 5.77 m can be completely identified by a triangular grid. The proposed sampling pattern and other geometric schemes were officially introduced into the field of soil survey and investigation of contaminated sites by the International Organization for Standardization (ISO) with their International Standard for Soil Quality Sampling, ISO 10381.[21] This standard serves as the design for sampling programs, for agreement between the customer and the contractor, or appropriate authorities, and for common action between the sampler and the analytical laboratory. The main emphases of the different parts of ISO 10381, and their relationship to the German standards for soil investigation, have been explained.[22] Additionally, some general remarks must be made about practical situations where it is not possible or desirable to cover the entire project area or parts of it with a regular grid. This can result in an irregular geometric arrangement of sampling points because of special conditions, such as morphology (rivers, lakes, mountains, railroad tracks), the distribution of property, curvilinear boundaries between estates, and so on. Some useful irregular patterns have been proposed.[23]

One surface sample each of grained slag was taken from the slagheap at each of 56 grid points of the equilateral triangle pattern at distances 10 m apart. Sampling from the remaining four points of the 60-point pattern was impossible because of sintered and crusted blocks and lumps. Additionally, eight individual surface samples were taken from each of ten different points of the pattern to accurately determine the chemical composition and physical properties of the slagheap and the error of sampling. Subsurface samples were obtained by percussion coring at 18 points of an equilateral triangular grid, each side of which was $dx = 20$ m long (see Figure 3). A percussion core 1 m long was considered to be an individual sample. Taking into account the

Figure 3 Area of the circumscribed circle and the corresponding radius belonging to the cells of a rectangular grid (a) and of a grid of equilateral triangles (b).

inside diameter of the percussion coring tube (40 mm) and an average bulk density of 1.1 g cm^{-3}, the mass of an individual sample was about 1.4 kg. In practice, a lower sample mass caused by unavoidable core loss during boring has been taken into account. Because of the high iron content and the predominantly grained structure of the slag, the masses and the numbers of samples were compared with the International Sampling Guidelines for Iron Ores, ISO 3081,[24] and with the German standard for sieve analysis from the Deutsches Institut Für Normung (DIN) 18123.[25] According to these standards, the required sample mass and the minimum number of samples depend on the maximum grain size, the grain size of the sieve curve at 5% oversize.

In the case of the granular rotary furnace slag, a maximum grain size of 2.5–25 mm was obtained using sieve analyses of the eight surface samples from each of the ten sampling points. Taking these data as a basis, DIN 18123 requires a minimum mass for an individual sample of 0.2–3 kg, (see Table 1). The ISO 3081 standard calls for a mass of 0.3–4 kg under these conditions (see Table 2). In addition, this standard prescribes 180 individual samples for a test material mass of 70–100 kt. Following these recommendations, six or seven samples

Table 1 Minimum sample masses required for different grain sizes, according to the German guidelines DIN 18123[25] for the determination of the sieve curve of granular materials

Maximum grain size (mm)	Minimum sample mass (kg)
2	0.15
5	0.30

150–200	190.00
Mass of consignment (t)	**Number of individual samples**
45 000–70 000	160
70 000–100 000	180
100 000–150 000	200
150 000–210 000	220

from each of the 18 grid points of the percussion coring investigation are necessary, in addition to the 56 surface samples. Therefore, the sampling strategy chosen by us did not contradict the regulations now valid for bulk solids handling.

Appropriate rules are lacking for sampling extremely heterogeneous wastes, as has been repeatedly emphasized.[26,27] General guidelines are being developed for sampling wastes but at most they contain only rough information. An overview of the European standards in this field is given by Knoop.[28] These standards require chemical analyses, which unfortunately have not yet been controlled by corresponding regulations and European standards. Until now, regulations for the chemical analysis of wastes have been used, which have been developed only for water, soil, sludge and sediments or for materials handled in the fuel and mineral oils industry. However, there are exact regulations regarding the chemical analyses of contaminated soils, such as the German Deutsche Einheitsverfahren (DEV) standards for water, sludges and sewage, but rules for the sample mass and the number of samples at contaminated sites are not included. The guidelines only contain general information. Consequently, the legal status of a person doing sampling (a sampler) is quite a problem. For a detailed consideration of this aspect, consult Krutz and Niessing.[29] The judicial consequences resulting from incorrect decisions by the sampler have been discussed in detail.[30,31]

For the sample mass, the German guideline and PN 2/78K of the Länderarbeitsgemeinschaft Abfall (LAGA)[32] require that the minimum mass of an individual sample (in kg) is 0.06 times the maximum grain size (in mm). In the present situation (a maximum grain size between 2.5 and 25 mm), a minimum sample mass of 0.15–1.5 kg is recommended. This guideline also contains instructions for the number of samples required depending on the range of maximum particle sizes, the mass of the consignment and the delivery of the waste (see Table 3). Following these instructions, a maximum of 15 individual samples should be taken. Of course, this number is too small in the present case. However, the requirements of the German TA Abfall (Technical Instructions for Wastes)[33] are even more unrealistic. The TA Abfall modified and simplified the sampling instructions of the LAGA guideline PN 2/78K as follows. First, the waste classes ''delivered within containers'' and ''delivered without containers'' are distinguished. Second, waste delivered without containers is classified by appearance, as homogeneous or heterogeneous. This places the rotary furnace slag in the class of ''heterogeneous wastes being delivered to the dump without containers'', and therefore one individual sample of 1 kg mass per 5 t waste must be taken. For a slagheap of 80 kt total mass, 16 000 samples and a total sample mass of 16 000 kg would be necessary. This is a completely unreasonable recommendation.

3.1.3 Sample Preparation

3.1.3.1 Chemical Analysis and Granulometric Analyses Each individual sample was prepared in its final form by homogenization, splitting and reducing. The splitting and reduction involved a three-fold coning of the sample material and subsequent quartering of the final cone using a splitting cross. The two opposite quarters of the cone were used as final samples for chemical and granulometric analyses. The quarters were weighed, and the concentrations of certain chemical components and their elution behaviors were obtained using the DEV standards for water, sludges and sewage.[34] To determine the ignition loss, a German standard for foundation testing was applied. An overview of the DIN standards and the related United States Environmental Protection Agency (USEPA) standards applied for the investigation of waste is given in Table 4. Further details have been provided by Hein and Kunze.[35] The concentrations of the heavy metals Fe, Zn, Pb, Cu and Cd and the As content were analyzed by acid decomposition and subsequent AAS. The S content was determined by an oxidizing melting decomposition with $Na_2CO_3/K_2CO_3 + Na_2O_2$ according to DIN 38405, part 5.[36] The sulfur compounds were converted to water-soluble sulphates, and the barium chloride added to precipitate the sulphates was quantitatively measured by weighing. The ignition loss, a measure of the combustible matter, was determined at temperatures of 550 °C and 1000 °C, according to DIN 18128.[37] Additionally, the grain size distribution was obtained by sieve analysis following DIN 18123.[25]

Different strategies were used for sample preparation and analysis depending on the available sample mass

Table 3 Instructions relating to sample masses from German (LAGA) sampling guidelines valid for wastes[32]

Range of maximum particle sizes	Minimum number of individual samples					
	From moved waste		From stationary waste			
			In trucks	In deposits		
	Mass of consignment			Mass of consignment		
	up to 50 t	>50 t	3	up to 50 t	50–150 t	>150 t
<20 mm	3	3 every 50 t	per	3	3 every 50 t	8
>20 mm	5	1 every 10 t	truck	5	1 every 10 t	15

Minimum sample mass = 0.06 × maximum particle size.

in order to provide all the chemical and physical characteristics needed. The strategy used for a percussion core sample with a mass between 400 and 900 g is shown in Figure 4. Another variant for samples with a mass greater than 900 g was covered previously.[14] The preparation and analysis schemes used for repeated surface sampling and for a single sampling of surface points, respectively, are shown in Figure 5. According to these schemes, the grain size distribution and the ignition loss were determined for the respective first and fourth quarters of the eight individual samples from ten surface points, as a first step. Afterwards, the residuals of the handled first and fourth quarters and the untouched second and third quarters of these eight samples were mixed, and a composite sample was obtained.[14] Finally, the composite sample was prepared and analyzed as a single surface sample. In this way, 10 composite samples and 46 single surface samples were investigated.

3.1.4 Statistical Analysis of Data

3.1.4.1 Geostatistics The chemical composition of the rotary furnace slag was evaluated from the original surface sampling data and from the percussion coring data obtained at fixed depths. To explain the spatial variability of the chemical components, variograms were constructed. The technique of point kriging was used to predict additional values of these quantities at points inaccessible for sampling and observation.

Let G be the set of all possible points of the slagheap. Both the construction of the variogram and the technique of kriging are based on the proposition[38] that for any measuring quantity Y_t, $t \in G$ at a point t in G is a regionalized variable.[39] Following this theory of the regionalized variable, Y_t is locally a random variable, and the set of all measuring quantities $\{Y_t\}_{t \in G}$ globally describes a random field. The random field is characterized by its expected values EY_t at points t and by the covariances $\mathrm{cov}(Y_t, Y_{t+\tau})$ which describe the correlation between two measuring quantities obtained in the different locations t and $t+\tau$ of the heap G. This random field is assumed to have second order homogeneity, i.e. the expected value of any measuring quantity Y_t in the total heap G is equal to a constant μ. The covariance cov(.,.) observed in a particular direction does not depend on the absolute locations t and $t+\tau$, but is a function only of the distance τ between the locations. This is mathematically expressed by Equations (1) and (2).

$$EY_t = \mu \qquad \text{for all } t \in G \tag{1}$$

$$\begin{aligned} \mathrm{cov}(Y_t, Y_{t+\tau}) &= E[(Y_{t+\tau} - \mu)(Y_t - \mu)] \\ &= C_Y(\tau) \quad \text{for all } t \in G \end{aligned} \tag{2}$$

C_Y is called the *covariance function* of the random field.

Figure 5 Scheme of preparation and analysis in repeated surface sampling and single sampling of surface points.

3.1.4.2 The Variogram Because the variances D^2Y_t und $D^2Y_{t+\tau}$ are equal to the covariance $C_Y(0)$ at a distance 0, the assumptions of homogeneity in Equations (1) and (2) respectively imply the following relationship between the variance and the covariance (Equation 3):

$$\begin{aligned} V(\tau) &= E[Y_{t+\tau} - Y_t]^2 = E[(Y_{t+\tau} - \mu) - (Y_t - \mu)]^2 \\ &= E[Y_{t+\tau} - \mu]^2 + E[Y_t - \mu]^2 - 2E[(Y_{t+\tau} - \mu)(Y_t - \mu)] \\ &= 2[C_Y(0) - C_Y(\tau)] \end{aligned} \tag{3}$$

The function V is called the *variogram function* of the random field, and it is twice the *semivariogram function* γ, as shown in Equation (4).

$$\gamma(\tau) = 0.5V(\tau) = C_Y(0) - C_Y(\tau) \tag{4}$$

In the following, the variance $D^2Y_t = C_Y(0)$ is represented as the simplified term S_Y^2.

The variogram function is a continuous one. Usually, this function is not immediately known and only its estimation at discrete distances is available (called the *empirical variogram function*). This estimation is obtained as follows. Let j and $j + \tau$ be any locations and Y_j and $Y_{j+\tau}$ the corresponding measurable values in these locations, respectively. Then, the value of the empirical variogram function at the distance τ is given by Equation (5).

$$\hat{V}(\tau) = \frac{1}{n(\tau)} \sum_{i=1}^{n(\tau)} [Y_{i+\tau} - Y_i]^2 \tag{5}$$

Here, $n(\tau)$ is the number of pairs of measuring values obtained at a distance τ from each other. Sufficiently accurate estimations of the variogram function must be based on a large number of data pairs. At least 50 data pairs are necessary as a general rule.[40] For example, in a pattern of n_0 points arranged as k equilateral triangles, whose sides are $\tau = \tau_{\min}$ long ($\tau_{\min} = 10\,\text{m}$ for the surface sampling and $\tau_{\min} = 20\,\text{m}$ for the percussion coring) exactly $n(\tau_{\min}) = n_0 + k - 1$ pairs of points are available for the variogram estimation at the minimum distance $\tau = \tau_{\min}$.

The empirical variogram function was fitted to an appropriate theoretical model to evaluate the spatial variability. The appearance of a variogram is characterized by the following structural parameters of the model:

V_{total} = the total variance, calculated as the mean squared deviation of all the data from the overall mean; C_0 = the nugget effect describing the maximum variance of immediately adjacent measuring quantities (it is caused by the error in sampling and by the spatial variability in the microscale region of the site to be investigated); a = the range (correlation length, radius of influence), i.e. the minimum spatial distance between uncorrelated measuring quantities; S_Y^2 = the sill, i.e. the maximum variance of uncorrelated measuring quantities; τ = the lag, i.e. the spatial distance between subsequent values of the variogram function.

These parameters occur in different models.[41] With chemical data from contaminated soils and waste sites, the spherical model (cubic model, Matheron's model[42]) is frequently used successfully (Equation 6).

$$\gamma(\tau) = 0.5V(\tau) = \begin{cases} 0 & \text{for } \tau = 0 \\ C\left(\frac{3}{2}\frac{|\tau|}{a} - \frac{1}{2}\left(\frac{|\tau|}{a}\right)^3\right) + C_0 & \text{for } 0 < \tau \le a \\ C + C_0 & \text{for } \tau > a \end{cases} \tag{6}$$

In addition to the parameters explained above, $S_Y^2 = C + C_0$ is the sill and C is the partial sill. In Equation (6), $\gamma(0) = 0$ is explained for continuous dependence of the measuring quantity on the lag τ. Mathematically, it follows from Equations (3) and (4). If $\gamma(\tau) \to C_0 > 0$, as $\tau \to 0$, then C_0 is the *nugget effect* (named by Matheron).[42] This is because it is believed that a variation at very small distances (microscale variation) caused by small nuggets generates a discontinuity at the origin of the data. But the only possible reason for such a phenomenon is an error of observation in both sampling and chemical analysis. Hence, the nugget effect is unverifiable without samples that are very close together. Following this idea, eight surface samples were taken from each of ten points of the slagheap. The mean squared deviation of the replicate values at a sampling point from the respective mean is an estimation of the variance of the sampling error. The error in chemical analysis is mostly assumed to be negligible without investigating the measuring process. In geostatistics, the nugget effect is determined by extrapolating variogram estimates from lags closest to zero. Its calculation is implemented in common geostatistical software following the recommendations of Cressie.[41] A more rigorous presentation of the nugget effect and its partitioning is available.[41]

An appropriate approximation of the sill $S_Y^2 = C + C_0$ is given by the sample variance in Equation (7),

$$S_n^2 = \frac{1}{n-1} \sum_{i=1}^{n} (Y_i - \overline{Y}_n)^2 \tag{7}$$

which is calculated on the basis of the total amount of n data of the series of measuring values, where $\overline{Y}_n$ is the overall mean.

Besides the spherical model, various parametric variogram models are applied in environmental science and pollution research. The following two basic isotropic models[43] are considered in terms of the semivariogram:

linear and exponential. They also include a possible nugget effect, as in the spherical model. A linear or an exponential variogram is recommended if there is a trend in the spatial behavior of the measuring quantity and if there are local anomalies in the chemical composition, or if there are polymodally or asymmetrically distributed measuring values.

The linear model is given by Equation (8)

$$\gamma(\tau) = \left\{ \begin{array}{ll} 0 & \text{for } \tau = 0 \\ C_0 + b_l|\tau| & \text{for } \tau > 0 \end{array} \right\} \tag{8}$$

where $b_l \geq 0$ is the slope of the function which holds when $C_0 \geq 0$.

The exponential model is given by Equation (9)

$$\gamma(\tau) = \left\{ \begin{array}{ll} 0 & \text{for } \tau = 0 \\ C_0 + C_e \left(1 - \exp\left(-\dfrac{|\tau|}{a_e}\right)\right) & \text{for } \tau > 0 \end{array} \right\} \tag{9}$$

with parameters $C_0 \geq 0$, $C_e \geq 0$, and $a_e \geq 0$.

The isotropic variogram models described above (spherical, linear and exponential) have been successfully used to obtain an informative cartography of spatial heterogeneities of chemical pollutants in agricultural soils near industrial sites.[44–46] The influence of the sampling distance on the estimation of the nugget effect has been investigated.[47] The graph of the variogram function, the *variogram*, is used for practical conclusions. It gives more detailed information regarding the range of correlations and the magnitude of the local and global variability in the directions of investigation. For an anisotropic object of investigation, there are different variograms in different directions. Typical effects of anisotropy on the ranges found in the Saxon slagheap example have been presented.[18,19]

3.1.4.3 Point Kriging Geostatistics uses the technique of point kriging to calculate additional data at points inaccessible for sampling. The main principle of point kriging is to estimate the value $Y(t_0) = Y_{t_0}$ of the regionalized variable at an uninvestigated point t_0 as the weighted mean $\overline{Y}(t_0)$ of n measuring values Y_{t_i} observed at points t_i, where $i = 1, 2, \ldots, n$ (Equation 10)

$$\overline{Y}(t_0) = \sum_{i=1}^{n} w_i Y_{t_i} \tag{10}$$

The weights w_i are determined by side conditions which state that the expected value of $\overline{Y}(t_0)$ equals the unknown $Y(t_0)$, and that the variance of prediction of $Y(t_0)$ by $\overline{Y}(t_0)$ is as small as possible. The estimate $\overline{Y}(t_0)$ of $Y(t_0)$ is unbiased, as shown in Equation (11), because

$$E\left[\overline{Y}(t_0) - Y(t_0)\right] = 0 \tag{11}$$

Equation (12) then holds because of Equation (10),

$$E\overline{Y}(t_0) = E\left[\sum_{i=1}^{n} w_i Y_{t_i}\right] = \sum_{i=1}^{n} w_i E Y_{t_i} \tag{12}$$

and Equation (13) follows because of Equation (1).

$$E\overline{Y}(t_0) = \mu \sum_{i=1}^{n} w_i \tag{13}$$

Because $E\overline{Y}(t_0) = \mu$ holds, the weights have to fulfill the side condition shown in Equation (14).

$$\sum_{i} w_i = 1 \tag{14}$$

The variance associated with predicting unknown values using the weighted mean of known values is given by Equation (15).

$$\begin{aligned} \sigma^2_{\text{prediction}} &= E\left[\overline{Y}(t_0) - Y(t_0)\right]^2 = D^2\overline{Y}(t_0) \\ &= E\left[\sum_{i} w_i Y_{t_i} - Y(t_0)\right]^2 \end{aligned} \tag{15}$$

This variance can also be written in the form shown in Equation (16).

$$\begin{aligned} \sigma^2_{\text{prediction}} = \sum_{i=1}^{n}\sum_{j=1}^{n} w_i w_j \operatorname{cov}\left(Y_{t_i}, Y_{t_j}\right) - 2\sum_{i=1}^{n} w_i \\ \times \operatorname{cov}\left(Y_{t_i}, Y(t_0)\right) + E\left[Y(t_0)\right]^2 \end{aligned} \tag{16}$$

Equation (17) follows from Equation (16), because of the requirement of homogeneity (Equation 2),

$$\begin{aligned} \sigma^2_{\text{prediction}} = \sum_{i=1}^{n}\sum_{j=1}^{n} w_i w_j C_Y\left(|t_i - t_j|\right) - 2\sum_{i=1}^{n} w_i C_Y \\ \times \left(|t_i - t_0|\right) + C_Y(0) \end{aligned} \tag{17}$$

(where C_Y is the covariance function).

The requirement to minimize the prediction variance under the side conditions in Equation (14) provides a system of $n + 1$ linear equations in the weights w_i desired (Equation 18).

$$\begin{array}{cccccc} C_Y(|t_1 - t_1|) & C_Y(|t_1 - t_2|) & \ldots & C_Y(|t_1 - t_n|) & 1 & \\ C_Y(|t_2 - t_1|) & C_Y(|t_2 - t_2|) & \ldots & C_Y(|t_2 - t_n|) & 1 & \\ \vdots & \vdots & & \vdots & 1 & \\ C_Y(|t_n - t_1|) & C_Y(|t_n - t_2|) & \ldots & C_Y(|t_n - t_n|) & 1 & \\ 1 & 1 & \ldots & 1 & 0 & \end{array} \times \begin{array}{c} w_1 \\ w_2 \\ \vdots \\ w_n \\ \lambda \end{array} = \begin{array}{c} C_Y(|t_1 - t_0|) \\ C_Y(|t_2 - t_0|) \\ \vdots \\ C_Y(|t_n - t_0|) \\ 1 \end{array} \tag{18}$$

This equation system has a unique solution if the determinant of the system matrix on the left of Equation (18) is nonzero. The complementary quantity λ is the Lagrange parameter, associating the weights w_i, (where $i = 1, 2, \ldots, n$), with the side condition that they total 1. The prediction variance has the value given by Equation (19).

$$\hat{\sigma}^2_{\text{prediction}} = C_Y(|t_0 - t_0|) - \sum_{i=1}^{n} w_i C_Y(|t_i - t_0|) - \lambda \quad (19)$$

Because of Equation (4), the covariance function C_Y is expressed by either the semivariogram function γ or the variogram function V. Therefore, the kriging technique which generates additional data in inaccessible points serves a double purpose: (1) to provide the data necessary to model the spatial variability of the measurable quantities in the object investigated; and (2) to formalize the estimated variogram function.

The step-by-step realization of the strategy ''estimation of the variogram function, calculation of new values by point kriging'' leads to a theoretically sufficient number of data, but only the empirical variogram allows us to conclude whether or not the results of the kriging are useful. In the case of an abnormal variogram function contradicting the theoretical assumptions of a homogeneous random field, the geostatistical theory is insufficient. The variogram function is abnormal if its values decrease as the distance increases after an increasing period or if there is generally no recognizable structure. An interpretation of the calculated results is irresponsible in such cases.

Frequently, no distinction is made between the terms variogram and semivariogram because the connection between them is clearly defined by Equation (4).

For a detailed derivation and discussion of kriging techniques, consult Journel and Huijbregts[43] and Cressie.[48] A concise presentation of geostatistics in general and kriging in particular is given by Journel,[49] and its application to site investigations is covered by Rocklin and Jauzein.[50]

3.1.4.4 Results

Surface Sampling. The iron, cadmium, lead, zinc and sulfur levels obtained in eight different directions of the slagheap were evaluated. The numerical calculations were carried out by using the computer program Surfer.[51]

The variograms of the copper content and the iron content vary considerably in different directions. Useful results were calculated in the west–east extension. Because of the finely-dispersed spatial distribution of copper within the slag there was no nugget effect, i.e. no microscale variation caused a discontinuity of the copper content at a sampling point. The sills and the ranges are of the same order of magnitude. This shows the isotropic behavior of the copper content in this extension.

The variogram and the three-dimensional graph of the iron content, calculated on the basis of the original data in the direction mentioned and the three-dimensional graph after kriging, are shown in Figure 6, as an example. A partial sill of $C = 17.0\%^2$ and a range of $a = 30\,\text{m}$ were obtained. The fitted spherical model has a nugget effect of about $C_0 = 3.0\%^2$. The figures written near the function points of the variogram represent the respective numbers of pairs of measuring values used to calculate the corresponding function value at the respective distance (Figure 6a). The three-dimensional graph of the data visualizes the spatial distribution of the iron content on the heap surface (Figure 6b). The local anomalies characterize extreme iron contents and they clearly stand out against the globally inherent iron distribution on the heap surface. The anomalies reflect the original data obtained at the sampling points, but the overall spatial variability is easily recognizable.

In contrast, useful empirical variograms were obtained for both the sulfur content and the zinc content in all directions by a stepwise change of the directions investigated. In principle, the three-dimensional graphs of both the sulfur and zinc contents are similar to that of the iron content, in some directions. This may be caused by the mineralogical composition of the thermally processed ore concentrates, the residue of which is the rotary furnace slag.

Furthermore, the following effect was observed in the spatial variability of the sulfur and the zinc contents. All the variograms have one and the same sill but different ranges depending on the direction searched. The set of ranges forms the boundary points of an ellipse in the given coordinate system. This effect is called a *geometric anisotropy*. The largest range was observed in the east-north-east direction, with the ratio of the largest range to the smallest one amounting to 2.6. The direction of the largest range and the ratio were used to transform the coordinates of the investigated area so that the transformed area was considered isotropic and consequently fulfilled the assumption of the kriging technique. Convincing three-dimensional graphs of the original data and the kriging values were obtained.

As for the lead content, semivariograms with no valuable structure or at least an untypical appearance were calculated. It was proved that the empirical variograms are fitted by a set of spherical model functions whose parameters may vary over wide intervals without any significant change in the goodness of fit. For a detailed discussion of this fact, see Rasemann and Herbst.[19]

The arsenic and cadmium contents also proved to be untypical of the chemical composition of the slagheap. The semivariograms calculated were either difficult to

Figure 6 Geostatistical evaluation of the iron content using the original data from surface sampling in the west–east extension of the slagheap. (a) Empirical semivariogram and corresponding spherical model fitted with a nugget variance of 3.0%^{2}, a sill of 20.0%^{2}, and a range of 30 m, respectively; (b) three-dimensional graph obtained after point kriging.

evaluate or were useless. There was neither a preferred direction of variability nor any geostatistical similarity between different directions. The parameters of the fitted semivariograms varied considerably from distance to distance and from direction to direction without a recognizable systematic structure. The anomalous variograms of the arsenic and lead contents can be explained by local nested concentrations of these pollutants on the heap surface. Anomalies formed by environmental influences occurred after dumping of the slags. Thus, because of the high concentration of unburnt carbon, the slag was carbonized at a low temperature and volatile components such as arsenic and lead sublimated on the surface and formed corresponding chemical compounds. The frequency distributions are also polymodal and asymmetric. The lead content distribution of a normal slag is shown in Figure 7, as an example.

The ranges of the semivariograms were mostly larger than the minimum sampling distance of 10 m, i.e. more

Figure 7 Frequency distribution of the lead content of a normal slag obtained from all surface samples.

samples than needed for a simple random sampling analysis using correlated data were taken. The available data generally gave grounds for a geostatistical analysis, but the number of values was insufficiently small in some

cases, and the errors expected were then too large for a reliable interpretation.

Percussion Coring. One sample was taken at every meter depth from percussion coring wells at 18 points of a regular pattern of equilateral triangles whose sides were 20 m long. The chemical components of samples from the same depth interval were geostatistically evaluated. The iron, copper, sulfur, cadmium, arsenic, and lead contents and the ignition loss were investigated. In general, both variograms and kriging structures obtained were similar to those for the surface sampling. In the following, some results from the 1–2 m depth interval are discussed.

The variograms and three-dimensional graphs obtained after kriging were especially valuable for the iron, sulfur and zinc contents in the west–east extension. In this orientation, structures of the spatial variability were traced even from the heap surface. But there are also directions in which the variograms are completely useless. To demonstrate this, the results of geostatistical evaluations of the zinc content obtained in the northerly direction are discussed. In Figure 8(a), an empirical semivariogram is presented. It was calculated only on the basis of the original data obtained from percussion core samples taken from 18 pattern points at a depth of 1–2 m. Between 2 and 17 pairs of measuring values were available to construct the points of the empirical

Figure 8 Geostatistical evaluation of the zinc content using the original data from percussion coring in the north extension of the slagheap. (a) Empirical semivariogram and corresponding spherical model fitted with the nugget variance $C_0 = 1.32\%^2$, the partial sill $C = 3.74\%^2$, and the range $a = 27.75\,\text{m}\%^2$; (b) three-dimensional graph on the basis of the original data and the calculated kriging values.

variogram. Because of the relatively small number of original data points, the error in the calculated results was correspondingly large. A spherical model with a nugget effect $C_0 = 1.32\%^2$, a partial sill $C = 3.74\%^2$, and a range $a = 27.75$ m was fitted. Using this model, point kriging was carried out. Figure 8(b) represents the corresponding three-dimensional plot. Obviously, this plot reflects only the original data and those in the neighbourhood of the sampling points, in principle. However, the data from this neighbourhood were inaccurate, because the distances between the original points were so large that the kriging procedure only provided an interpolation between the original data and the overall mean. This conjecture has been examined previously for a similar situation involving the evaluation of the iron content.[14,19] Therefore, for a mainly heterogeneous slagheap with wide distances between adjacent sampling points, the technique of point kriging must not be used to model the spatial variability of the chemical composition.

The spatial variability of the sulfur content was accurately represented by geostatistical methods. Structures obtained were similar to those of the surface sampling. No systematic dependence of the original data on their spatial allocation was observed for the cadmium content. Consequently, empirical (semi)variograms were obtained which could not be fitted by a single-value theoretical model function.

The use of percussion coring to evaluate the spatial distribution of the lead content provided no additional knowledge as compared with surface sampling. Empirical semivariograms calculated on the basis of 2–16 pairs of original data sets were found which are better fitted by an exponential function than by a spherical model (as an example see Figure 9a). Because of the finely-dispersed

Figure 9 Geostatistical evaluation of the lead content obtained by percussion coring in the depth interval of 1–2 m in the west–east extension of the slagheap. (a) Empirical semivariogram and fitted spherical model with the nugget effect $C_0 = 0\%^2$, the sill $C = 0.847\%^2$, and the range $a = 23.04$ m; (b) three-dimensional graph of the original data and the values calculated by kriging on the basis of the fitted model in (a).

distribution of lead within the slag, a nugget variance was not observed. Theoretically the kriging procedure with a fitted spherical function provided additional data, on the basis of which a three-dimensional picture of the spatial variability was obtained (Figure 9b). But because of the small number of original data, the large distances between the neighboring sampling locations and the unavoidable errors of variograms and kriging, the validity and usefulness of the geostatistical conclusions were questionable.

Random Sampling Analysis. It was shown that the spatial variability of a chemical component of the slagheap cannot be successfully evaluated by geostatistical methods if this component is heterogeneously distributed over the heap. To avoid this, and to guarantee that the geostatistical assumptions (i.e. a homogeneous isotropic random field), are more likely to be fulfilled, the entire slagheap can be partitioned into several relatively small subregions. However, this procedure requires a more close-meshed sampling pattern to provide the data necessary for a reliable geostatistical evaluation.

If a detailed characterization of the slagheap is too expensive compared with the benefit expected, and the localization of highly contaminated subregions is impossible or unnecessary, the spatial location of any datum point obtained is not of interest. In such cases, random sampling analysis is recommended. Using random sampling analysis, the original data are assumed to be randomly located and stochastically independent. Independent variables are also uncorrelated. Then, the slagheap is globally evaluated by estimating the overall true content (expectation value) and the variance of the original data. The true content is estimated by the overall mean of all data available. The absolute difference between the mean and the (unknown) true value defines the absolute error (accuracy) of estimation. If an upper bound of this error and a lower bound of its confidence probability are prescribed, the minimum number of randomly located samples necessary to fulfill these limitations can be calculated.

For example, let μ be the true content of a component. Furthermore, let $\overline{Y}_n$ be the mean and S_n^2 be the empirical variance obtained by n samples, respectively. $\overline{Y}_n$ and S_n^2 are random variables. Here and in the following, the random variables are represented as capital letters, and the corresponding actual values are written as lower-case letters. Hence s_n^2 is the actual value of the empirical variance S_n^2, and $\bar{y}_n$ is the actual value of the mean $\overline{Y}_n$. The true content μ is not known, as a rule, but it can be replaced by the mean $\overline{Y}_n$. In doing so, an error is made. The difference between the mean and the true value is called the *absolute error of estimation* or the *accuracy of prediction*, and this error is denoted as $|\overline{Y}_n - \mu|$. This error is a random variable with an expected value of zero and a standard deviation $S_n/\sqrt{n}$. As the standard deviation S_n is the mean error of any individual observation, the quantity $S_n/\sqrt{n}$ is the mean error of the mean $\overline{Y}_n$. The mean error of the mean is abbreviated as $S_{\overline{Y}_n}$. A random interval which covers μ at the confidence probability (confidence level) β is defined by Equation (20).

$$\overline{Y}_n - \frac{S_n}{\sqrt{n}} t_{n-1;(1+\beta)/2} < \mu < \overline{Y}_n + \frac{S_n}{\sqrt{n}} t_{n-1;(1+\beta)/2} \quad (20)$$

Here, $t_{n-1;(1+\beta)/2}$ is the quantile of the order $(1+\beta)/2$ of the Student's t-distribution at the degree of freedom $n-1$; this value can be found in tables of mathematical statistics.[4] Furthermore, by rearranging Equation (20), an upper bound of the absolute error of estimation $|\overline{Y}_n - \mu|$ at the confidence probability β is obtained (Equation 21).

$$\varepsilon_n = \frac{S_n}{\sqrt{n}} t_{n-1;(1+\beta)/2} \quad (21)$$

The quantity ε_n is called the *probable error of estimation* of μ by $\overline{Y}_n$ at the confidence probability β. The confidence probability β is taken to be 90–95%, as mentioned above. In practice, an upper bound of the probable error of estimation, say ε_0, at a certain probability β is prescribed. That is, a quantity ε_0 is required which fulfills the condition $|\overline{Y}_n - \mu| \leq \varepsilon_0$ at the probability β. This bound is called the *maximally admissible error of estimation*. Substituting ε_0 for ε_n and n_0 for n in Equation (21), the inequality shown in Equation (22) is obtained.

$$\varepsilon_0 \leq \frac{S_{n_0}}{\sqrt{n_0}} t_{n_0-1;(1+\beta)/2} \quad (22)$$

If an estimated value s_n of S_{n_0} is known, and if for $t_{n_0-1;(1+\beta)/2}$ an approximate value of 2.00 at confidence probability 95% is taken, the minimum number of samples n_0 necessary to fulfill the condition in Equation (22) is obtained according to Equation (23).

$$n_0 \geq 4\frac{s_n^2}{\varepsilon_0^2} \quad (23)$$

For the special case where the admissible error of the mean must not be greater than the mean error of any individual observation ($\varepsilon_0 = s_n$), at least $n = 4$ samples are needed. To be sure that this requirement is fulfilled even with one outlier, five samples are taken in practice. If the stronger condition $\varepsilon_0 = s_n/2$ is required, $n = 16$ samples are needed.

The procedure explained above was applied to globally evaluate the lead content of the slagheap. A number $n = 54$ of surface samples were considered. The mean value $\bar{y}_n = 0.98\%$, the empirical variance $s_n^2 = 0.18\%^2$ (see Equation 7) and the standard deviation $s_n = 0.42\%$

were calculated. The two-sided quantile of the Student's t-distribution with a degree of freedom $n-1=53$ at a confidence level of 95% is $t_{53;0.975}=2.0057$. A quantile of a distribution function at the confidence level β is called two-sided or two-tailed if the relation $t_{(1-\beta)/2}=t_{(1+\beta)/2}$ holds. This is fulfilled when the distribution is symmetrical to the expectation value zero. By putting the t-value, the actual mean $\bar{y}_n=0.98\%$ and the empirical variance $s_n^2=0.18\%^2$ into Equation (20), the interval (0.86%, 1.10%) was calculated. This interval covered the true lead content at a probability of 95%. This estimate corresponds to an accuracy of prediction of $\varepsilon_n=0.12\%$. When $\varepsilon_0=0.10\%, n_0\geq 4\times(0.18/0.01)=72$ samples are needed. To guarantee this accuracy, the 56 surface samples and one sample from each of the 18 percussion coring wells would have been sufficient if the standard deviation s_n had not been changed considerably.

If the situation allows gradual sampling, chemical analysis and statistical evaluation of the data the number of samples needed for a prescribed precision of estimating ε_0 at a given confidence probability β can be sequentially determined in the following way. Let n be the minimum number of samples available at the beginning of the investigation, say $n=5$ as an example. Then, the mean $\bar{y}_n$, the error of the mean $s_{\bar{y}_n}$ and the probable error of estimation ε_n are calculated. If $\varepsilon_n<\varepsilon_0$ holds for a prescribed ε_0 at a given confidence probability β, the investigation is finished. If it is not, additional samples are taken, the statistical parameters $\bar{y}_n$ and $s_{\bar{y}_n}$ are calculated and the actual probable error of estimation, ε_n, is compared with the given maximum admissible error of estimation ε_0. The investigation is continued until the condition $\varepsilon_n<\varepsilon_0$ with the actual number of samples n is fulfilled.

Figure 10 shows a graphical presentation of the mean lead content $\bar{y}_n$ and the lower and upper confidence limits $\bar{y}_n\pm\varepsilon_n$ for the true content μ at a confidence probability

Figure 10 Graphical presentation of the sequential estimation of the expected lead content assuming uncorrelated observations.

95% against the number of samples n. The influence of possible outliers and extreme values on the estimation process obviously decreases as the number of samples increases, as expected.

Finally, let us compare the benefit of a random sampling method with a systematic method. As mentioned above, the error of the mean $s_{\bar{y}_n}$ measures the efficiency of a sampling method. In contrast to random sampling analysis, the systematic method takes into account the allocation of the data in space. For a data series consisting of n subsequently allocated data points, the squared error of the mean is calculated according to Equation (24).

$$S_{\bar{Y}_n}^2=\frac{S_Y^2}{n}\left[1+\frac{2}{n}\sum_{\tau=1}^{n-1}(n-\tau)K(\tau)\right] \tag{24}$$

In this equation, besides the quantities explained above, $K(\tau)$ is the value of the correlation function K describing the degree of correlation (correlation coefficient) of each of two measuring variables observed at a spatial distance of τ from each other.

Obviously, the error of the mean increases as the correlation coefficient between the variables at different sampling locations increases. The correlation function K is immediately related to the semivariogram function γ or the variogram function V. Because of Equation (4), and $S_Y^2=C_Y(0)$, the value of the semivariogram function at the lag τ is expressed as shown in Equation (25).

$$\gamma(\tau)=S_Y^2\left[1-\frac{C_Y(\tau)}{S_Y^2}\right] \tag{25}$$

Here, $C_Y(\tau)/S_Y^2$ is the value of the correlation function K mentioned, and this quantity is abbreviated as $K(\tau)$. Equation (26) thus results from Equation (25) as follows.

$$K(\tau)=1-\frac{\gamma(\tau)}{S_Y^2} \tag{26}$$

Substitution of Equation (26) for $K(\tau)$ in Equation (24) gives Equation (27).

$$S_{\bar{Y}_n}^2=\frac{S_Y^2}{n}\left[1+\frac{2}{n}\sum_{\tau=1}^{n-1}(n-\tau)\left[1-\frac{\gamma(\tau)}{S_Y^2}\right]\right] \tag{27}$$

This equation emphasizes the connections between random sampling analysis and geostatistical analysis. In practice, the mostly unknown variance S_Y^2 in Equations (24) and (27) is replaced by the respective estimate S_n^2 obtained according to Equation (7). In the special case of no correlations at any lag ($K(\tau)\equiv 0$ for any τ), the semivariogram function γ already has its maximum, actually S_Y^2, at the minimal lag $\tau=1$. Substituting S_Y^2 for $\gamma(\tau)$ at any lag τ in Equation (27), and considering that $\sum_{\tau=1}^{n-1}(n-\tau)=n(n-1)/2$, the expression

$S^2_{\overline{Y}_n} = S^2_Y/n$ describing the squared error of the mean of n randomly chosen variables results from Equation (27). This error is lower than any other error calculated by Equation (27) on the basis of the same number of correlated data. Thus, time-consuming and costly geostatistical planning and sampling experiments to investigate extremely heterogeneous heaps and wastes is justified only for compelling reasons, for example if there is a particularly great interest in evaluating the spatial variability of certain regions. Otherwise, random sampling analysis is preferred. In the case of the Saxon slagheap, a sampling distance in the same order of magnitude as the range (correlation length) should be chosen.

3.1.5 Summary and Conclusions

In some cases sampling according to a systematic pattern followed by geostatistical evaluation can be successfully used to obtain a realistic picture of the spatial variability of the slagheap. Empirical (semi)variogram functions were calculated using original data in definite directions of the field of investigation and in fixed levels of the heap. The empirical variogram functions were fitted by a spherical model. Nugget effect, sill and range were easily interpretable parameters of this model. The technique of point kriging was applied to calculate data for additional points on the basis of the fitted variogram functions. Using the original data and the calculated values, three-dimensional presentations show the spatial variability of essential chemical components such as iron, zinc and lead. Useful results were obtained for the sulfur content in all directions and all levels. The geostatistical evaluation of the iron content only provided valuable variograms and kriging data in some directions of the heap. However, the iron content varied so widely in other directions that geostatistical methods did not work there either. The cadmium and the arsenic contents were untypical of the composition of the slagheap. The semivariograms calculated were either difficult or impossible to evaluate and showed neither preferred directions of variability nor any geostatistical regularity.

To sum up, it can be concluded that the highly expensive sampling, chemical analysis and geostatistical evaluation of extremely heterogeneous heaps of slags and industrial wastes are justified only by compelling reasons. However, reasonable results are obtained even with the wrong assumptions, because many geostatistical procedures are fairly robust. On the other hand, sampling regulations based on relationships between grain size and sample mass fail for contaminated sites and wastes where the structure has been markedly changed by physical and chemical processes, such as leaching, carbonization at low temperatures, precipitation, etc. If a global evaluation of the heap by mean values and variances of certain chemical components has priority, however, the usual methods of sampling and statistical data analysis recommended and developed for bulk materials and soils are promising tools.

The methodical results obtained from evaluating extremely heterogeneous contaminated sites and wastes in the Saxon slagheap example clearly show the possibilities and limitations of known sampling methods and geostatistical models. On the one hand, probably the greatest disadvantage in applying geostatistics is the difficulty in knowing whether the assumptions, for example a homogeneous isotropic random field, are acceptable or not in an individual case. On the other hand, such a close-meshed sampling and percussion coring pattern as applied in the case of the Saxon slag heap cannot be realized under commercial conditions. In practice, a compromise must be made. A promising strategy is to lay a regular grid over the region so that the coordinate origin and axis orientation are random. Then, samples are taken either systematically at each grid point or randomly at each subsection of the pattern. As shown in the example of the slagheap, one advantage of systematic sampling using a randomly placed grid is that the data obtained are very suitable for analysis by random sampling and geostatistical methods.

3.2 Evaluation of a Mercury-contaminated Site – A Problem of Sampling and Sample Pretreatment

3.2.1 Introduction

To make decisions concerning contaminated sites, a reliable estimation of the environmental risk caused by hazardous components is necessary. This estimation can be performed by means of soil analysis, for instance. In this case, errors resulting from sampling, sample preparation and chemical analysis are unavoidable. To restrict these errors and to achieve comparable and legally valid criteria for the pollution levels, certain regulations must be considered.[52] Until recently such regulations have been available only for limited fields of application. The rules commonly used for the evaluation of contaminated sites were originally developed for soils, water, sewage and sludges. The DEV are methods relating to the investigation of water, sewage and sludges[34] and to sewage sludge regulation.[52] A detailed overview of the German, European and International standards used for the determination of physical properties and the composition of inorganic pollutants in soils is given in Tables 5, 6 and 7.[53] To apply these rules in soil quality estimation, it is assumed that:

1. the soil is in an area (potentially) suitable for agricultural or horticultural use;

2. the inorganic contaminants in particular are distributed relatively uniformly over the whole area investigated;
3. the concentrations are low and of the same order of magnitude as the geologically originated background containing mainly nonvolatile compounds.

In contrast, the hazardous components of contaminated sites can occur in high concentrations, be distributed nonuniformly over the area of investigation and be bound in analytically relevant amounts to volatile species. If there is improper handling of the soil samples after sampling, chemical analysis can result in concentrations that are too small. This problem is known and can be controlled by regulations existing for sample preparation and for analysis of volatile compounds such as halogenated hydrocarbons, chlorinated hydrocarbons, hydrocarbons and phenols.

The fact that heavy metals such as mercury can escape from the soil sample is so far not reflected in the regulations for sample preparation. Mercury is known to exist in several forms or species in the environment. For the evaluation of contaminated sites, volatile species are of special interest.[54]

1. All kinds of volatile mercury species such as elemental metallic Hg(0), methylmercury, dimethylmercury and phenylmercury, could be emitted by anthropogenic sources.[53]
2. Bacteria are able to transform Hg^{2+} into volatile methylmercury. This process is described for various environmental matrixes and conditions. Bacteria are also able to reduce Hg^{2+} to volatile Hg(0). In such cases, a high vapour pressure of metallic mercury is responsible for its volatilization as the soil sample drys up.
3. Methylmercury can be transformed into volatile Hg(0), methane and other organic compounds by microbial activity and by abiotic processes.
4. Hg^{2+} can be transformed into Hg(0) by abiotic reduction.
5. In addition, mercury and its species adsorb to different types of materials (e.g. plastic bags for soil samples), and are released in an uncontrollable manner.

The aim of our investigations was to find out, using an example, to what extent the analytically detectable mercury content of soil samples taken from contaminated sites is influenced by the handling of samples between sampling and sample preparation. Handling covers all the means by which the soil sample can be exposed, up to its preparation for chemical analysis. These procedures are termed *sample pretreatment* in order to distinguish them from *sample preparation* by homogenization, splitting and reduction. Thus, methods of storing the sample material under different natural conditions or even active procedures that change the physical or chemical structure of the sample material (such as thermal evaporation at different temperatures) also define sample pretreatment measures. However, the measured results can be influenced not only by sample pretreatment but

also by errors of sampling, sample preparation and chemical analysis. Finally, we must take into account the fact that, in practice, the measured mercury content should reflect the intrinsic properties of the soil sample. These properties depend on the sampling location and are subject to global and local variations. To obtain general statements, it was necessary to plan the investigation program such that the different possible causes for the variation in measuring results could be evaluated independently. Other chemical components besides mercury were not investigated.

3.2.2 Object Investigated, Experimental Design

An industrial mercury-contaminated site was chosen as an example. Three locations of the site were investigated, named as A, B and C. At each point, *primary samples* of about 2 kg were taken from depths of 0–10 cm and 10–25 cm, respectively. Each primary sample was homogenized and split into three *subsamples*. The subsamples were separated again, and each portion was submitted to different pretreatment conditions before chemical analysis. The material obtained is referred to as a *pretreated sample*. The pretreatment methods were:

(1) unchanged original material;
(2) air drying for 2–4 weeks;
(3) storing in a plastic bag for 2–4 weeks; and
(4) thermal evaporation at 40, 60, 80, 105 and 120 °C.

For air drying for 2–4 weeks, about 100 g of the wet soil samples were spread on porcelain plates in a mercury-free atmosphere in normal light and at room temperature (20 °C).

For storing in plastic bags for 2–4 weeks, about 100 g of the wet soil samples were placed into commercial plastic bags and stored in a mercury-poor atmosphere in normal light and at room temperature (20 °C).

For thermal evaporation at 40, 60, 80, 105 and 120 °C about 20 g of the wet soil samples were placed in porcelain pans. The pans were placed on a sand bath at the chosen temperature for 24 h in a mercury-poor atmosphere. The mercury content of the laboratory atmosphere was determined once a week and proved to be below 80 ng m^{-3}.

Two or three *final samples* of 3 g each were selected from each pretreated sample and digested by 10 ml HNO_3/HCl (Merck) for 4 h at 90 °C according to DIN 38414-7 (see Tables 6 and 7). All chemicals were of analytical grade. Water from a Milli-Q purification system was used throughout. A 20% m/V solution of tin(II) chloride in 15% HCl (Merck) was applied in the reduction step. The calibration was carried out using mercury(II) solution (Merck). A Perkin-Elmer (model 430) atomic absorption spectrometer, equipped with a MHS 20 mercury hydride system with amalgam attachment and a model 056 recorder (Spectraphysics) were used for the total mercury determinations.

The measuring results can be arranged in a hierarchical scheme as shown in Figure 11.

The total amount of samples from a sampling location is referred to as the *gross sample*. If the mean values are formed to each branch of a hierarchical level in the scheme shown in Figure 11, for a gross sample, a primary sample within a gross sample, a subsample within a primary sample, etc., the following questions arise.

1. Are the mean values of the gross samples significantly different from each other, i.e. does the sampling location significantly influence the mercury content?
2. Are the mean values of the primary samples of a particular gross sample significantly different from each other, i.e. does the sampling depth influence the results at a sampling location?
3. Are the mean values of the subsamples from one primary sample significantly different from each other, i.e. is sample preparation a statistically important source of error?
4. Given that pretreated samples from one subsample produce significantly different results, does the method of sample pretreatment influence the mercury content detected by chemical analysis?

The first question is easily answered: the means of the three sampling locations are significantly different, as the frequency distribution of the mercury content clearly shows (see Figure 12).

3.2.3 Statistical Analysis of Data

3.2.3.1 Variance Analysis The questions mentioned above are mathematically and statistically treated by a model of variance analysis of four-way hierarchical classification (because of the four classes of hierarchically ordered test conditions) with random effects (because the experimental conditions are chosen at random from a large number of possibilities) and with a balanced experimental design (each experimental condition of a certain hierarchical level is combined with the same number of experimental conditions of other hierarchical levels in every case). The principle of variance analysis is to reduce the comparison of mean values to the comparison of variances. These variances are obtained by splitting the *total variance* of the measured results into individual portions produced independently of each other by differences between sampling locations (global variations), between sampling depths of a sampling location (local heterogeneities), and by errors made in sample preparation, sample handling and chemical analysis. The following mathematical model can be given.

Figure 11 Hierarchical scheme of sampling conditions and measured results.

Figure 12 Frequency distribution of the mercury content at the sampling locations.

Two measured values were obtained for each pretreated sample. Let Y_{ijklm} be the mth measured value belonging to the lth pretreated sample of the kth subsample from the jth primary sample at the ith sampling location. Y_{ijklm} is thought to be decomposable as shown in Equation (28)

$$Y_{ijklm} = \mu + \alpha_i + \beta_{ij} + \gamma_{ijk} + \delta_{ijkl} + Z_{ijklm} \qquad (28)$$

with $i = 1, 2$; $j = 1, 2$; $k = 1, 2, 3$; $l = 1, \ldots 10$; $m = 1, 2$. μ is the overall expected value, estimated from the mean of all measuring results; α_i is the random effect caused by global fluctuations of the mercury content within the contaminated site, measured by the difference between the mean obtained from the values at the ith sampling location and the overall expected value; β_{ij} is the random effect caused by local heterogeneities of the contaminated site, described by the deviation between the ith gross sample mean and the respective jth primary sample mean, and is a measure of the random error of sampling; γ_{ijk} is the random effect of sample preparation, which describes the random deviation between the mean of the jth primary sample at the ith sampling location and the mean of the respective kth subsample obtained by homogenization and splitting of the material of the primary sample; δ_{ijkl} is the random effect of sample pretreatment, measured by the deviation between the mean of the lth pretreated sample and the mean of the corresponding kth subsample from which the pretreated material was separated; and Z_{ijklm} is the random error of analysis, which defines the deviation between the measured value Y_{ijklm} and the respective mean of the $ijkl$th pretreated sample.

The following assumptions are made: that the measured values Y_{ijklm} are normally distributed random variables with an expected value μ and a total variance σ^2_{total}, and that the effects α_i, β_{ij}, γ_{ijk}, δ_{ijkl} and the measuring error

Z_{ijklm} are normally distributed, mutually independent random variables with the expected value zero and respective variances σ_α^2, σ_β^2, σ_γ^2, σ_δ^2 and σ_Z^2 for all i, j, k, l and m.[55] Then, the total variance can be expressed as the sum of these individual variances as shown in Equation (29).

$$\sigma_{\text{total}}^2 = \sigma_\alpha^2 + \sigma_\beta^2 + \sigma_\gamma^2 + \sigma_\delta^2 + \sigma_Z^2 \tag{29}$$

The components in Equation (29) are the *variance components*. The following designations are used: $\sigma_\alpha^2 = \sigma_{\text{global}}^2$, $\sigma_\beta^2 = \sigma_{\text{local}}^2$, $\sigma_\gamma^2 = \sigma_{\text{preparation}}^2$, $\sigma_\delta^2 = \sigma_{\text{pretreatment}}^2$, and $\sigma_Z^2 = \sigma_{\text{analysis}}^2$. The quantity σ_{global}^2 represents the variance caused by global fluctuations of the mercury content over the site; σ_{local}^2 designates the variance by local heterogeneities and corresponds with the sampling error variance, in principle; $\sigma_{\text{preparation}}^2$ indicates particularly the variability between the mercury content of different subsamples obtained by homogenization and splitting of a primary sample; $\sigma_{\text{pretreatment}}^2$ describes the variance of the mercury content caused by the different methods of handling the subsamples before chemical analysis; and finally $\sigma_{\text{analysis}}^2$ is the variance of the error of chemical analysis.

The questions mentioned above regarding the influence of sampling conditions and handling of samples on the mercury content detectable by chemical analysis are reduced to significance tests of the respective variances. The statistical treatment of these questions can be done using analysis of variance (ANOVA).[55] The following results were obtained.[54,56]

1. The global fluctuations between the sampling locations of the contaminated site are highly significant. The variance σ_{global}^2 contributes about 88% to the total variance of the mercury content.
2. The local heterogeneity also significantly influences the mercury content, and its variance σ_{local}^2 amounts to 6% of the total variance. That is, the mean content at a location essentially depends on the depth from which the soil sample is taken. Generally, the mercury content near the soil surface is lower than that from deeper levels. This may be due to microbiotic changes of nonvolatile compounds into volatile species such as elemental metallic mercury, phenylmercury, methylmercury and others, and the leaching of soluble mercury salts.
3. The sample preparation variance $\sigma_{\text{preparation}}^2$ is nonsignificant. That is, the primary samples were split into statistically equivalent subsamples.
4. The sample pretreatment variance $\sigma_{\text{pretreatment}}^2$ is highly significant and of the same order of magnitude as the local heterogeneity variance. The error of sample pretreatment is three to five times greater than the error of the chemical analysis at a confidence probability of 95%. The chemical analysis variance $\sigma_{\text{analysis}}^2$ contributes less than 0.5% to the total variance.

3.2.3.2 Systematic Error of Pretreatment Variance analysis was used to *qualitatively* prove that handling of the soil samples significantly influences the mercury content detectable by chemical analysis. To decide *quantitatively* to what extent the mercury content of the original material is changed by a particular method of sample pretreatment, further statistical comparisons were carried out. More precisely, it was necessary to assess the error made if pretreated samples are used instead of the original material. Additionally, the probability of this error was evaluated. To find out the appropriate test procedure, the statistical properties of the mercury content were checked. Since the mercury content was normally distributed, pairwise comparisons of mean values seems to be reasonable. Because there was no significant error of sample preparation, the subsample variances of the measured values obtained for a fixed pretreatment method were summed up to the respective pretreated sample variance. As shown by Bartlett's test and Fisher's F-test,[4,57] the variances of different pretreated samples were proved to be statistically identical. That enabled us to use the two-sample t-test to compare the mean values obtained carrying out a fixed pretreatment method, with the respective mean of the unchanged original material of a primary sample. The comparisons were based on the following ideas.[56,58]

First, the pretreatment methods were arranged in a certain order to formally designate them by symbols or numbers. Now, let μ_1 be the true mercury content at a definite location and a definite sampling depth of the contaminated site, and μ_i the expected content after the ith method of pretreatment was applied to the original sample material ($i = 2, 3, \ldots$). The difference $|\mu_1 - \mu_i|$ is the systematic error which is made if the original material is not known and only the ith pretreated sample is available. Normally this error is not detectable, but the corresponding mean values $\bar{y}_1$ and $\bar{y}_i$ as well as the empirical variances s_1^2 and s_i^2 obtained by n_1 and n_i independent samples, respectively, are known. The quantities $\bar{y}_1$, $\bar{y}_i$, s_1^2, and s_i^2 are realizations of the respective random variables $\overline{Y}_1$, $\overline{Y}_i$, S_1^2, and S_i^2. Using them, a random interval can be given which covers the systematic error $|\mu_1 - \mu_i|$ at a prescribed confidence probability β (Equation 30).

$$I_\beta = |\overline{Y}_1 - \overline{Y}_i| \pm S\left(|\overline{Y}_1 - \overline{Y}_i|\right) t_{m;(1+\beta)/2} \tag{30}$$

Here, $t_{m;(1+\beta)/2}$ is the corresponding quantile of Student's t-distribution at the degree of freedom $m = n_1 + n_i - 2$,

and (as shown in Equation 31)

$$S\left(|\overline{Y}_1 - \overline{Y}_i|\right) = \sqrt{\frac{(n_1 + n_i)\ (n_1 - 1)S_1^2 + (n_i - 1)S_i^2}{n_1 n_i (n_1 + n_i - 2)}} \tag{31}$$

is the standard deviation (the mean error) of the mean value difference $|\overline{Y}_1 - \overline{Y}_i|$. The length $|I_\beta|$ of the interval I_β is termed the *probable systematic error at the confidence probability* β. Equation (32)

$$\varepsilon_\beta = \frac{|I_\beta|}{\mu_1} \tag{32}$$

is the corresponding *probable relative systematic error*. This criterion seems to be well suited to illustrate the change of the expected mercury content of a soil material after handling by the *i*th pretreatment method. Since the content of the original material μ_1 is mostly unknown, it must be replaced by an appropriate estimation such as the lower limit $\tilde{\mu}_{1,\beta}$ of the confidence interval for μ_1 at the confidence probability β obtained as shown in Equation (33)

$$\tilde{\mu}_{1,\beta} = \overline{Y}_1 - t_{n_1-1;(1+\beta)/2} \sqrt{\frac{S_1^2}{n_1}} \tag{33}$$

where $t_{n_1-1;(1+\beta)/2}$ is the quantile of Student's *t*-distribution at the degree of freedom $n_1 - 1$. The systematic error ε_β in Equation (32) is dimensionless and may be also given as a percentage.

Figure 13 compares the probable relative systematic errors caused by storing the sample in a plastic bag for 2–4 weeks, for samples from locations A and B at a sampling depth of 0–10 cm. A probable relative systematic error up to 40% may occur at a confidence probability of 95%. Storage of the soil samples in plastic bags for 2–4 weeks had the same effect as thermal evaporation at 40 °C. Generally, the absolute loss of mercury in a soil sample depends only on the method of handling and not on the original concentration or the sampling location. Therefore, the lower the original concentration, the greater the relative systematic error. Furthermore, this error increases as the confidence probability increases. Thus, the accuracy in determining the influence of sample preteatment on the mercury content detectable by chemical analysis at a given probability, and under fixed conditions of sampling and analysis, can be improved by decreasing the mean error of the mean value difference $S(\overline{Y}_1 - \overline{Y}_i)$ in Equation (31). This can be done by increasing the degree of homogenization of the samples and by increasing the numbers of samples, n_1 and n_i. Interlaboratory tests and intralaboratory tests must be done to improve the repeatability and the reproducibility of the instrumental measurements.[59]

Figure 13 Graphic representation of the *probable relative systematic error* ε_β *at the confidence probability* β caused by storing mercury-contaminated soil samples in plastic bags over 2–4 weeks taken at the locations A and B in the depth interval 0–10 cm each. ×, mean values for location A, original 446 mg kg^{-1}, plastic bag 425 mg kg^{-1}; ∘, Mean values for location B, original 189 mg kg^{-1}, plastic bag 153 mg kg^{-1}.

To qualify the results represented, it must be emphasized that the definite errors mentioned are valid only for the object investigated and must not be immediately transferred to any other contaminated site. However, they may serve as a basis for developing regulations for the handling of soil samples contaminated by volatile compounds and for introducing instruments to control the influence of the handling on the mercury content detectable by chemical analysis.

3.2.4 Summary and Conclusions

Using the example of a mercury-contaminated site, it was demonstrated that the handling of soil samples can affect the mercury content detectable by chemical analysis. To distinguish this effect from the errors of sampling, sample preparation and chemical analysis, as well as from the global and local effects of the geogenic background, the following sampling design was used. One soil sample (called the primary sample) was taken at two different depth intervals from each of three locations, and each primary sample was then split into three more portions, called subsamples. The subsamples were again separated into several parts, each of which was submitted to a particular method of handling before analysis. Every method of handling defines a method of sample pretreatment. One portion was kept as the unchanged original material, and its mercury content was immediately determined. The following methods of sample pretreatment were applied: air drying for 2–4 weeks; storing in plastic bags for 2–4 weeks; and thermal evaporation at different temperatures from 40 °C up to 120 °C. The pretreated samples were analyzed, and the mercury content detected was compared with the content of the respective original material.

First, variance analysis was applied to globally quantify by variances the effects of sample preteatment, sample preparation, global fluctuations, local heterogeneities and chemical analysis. The dominant source of variability was the global fluctuations of the mercury content. ''Global fluctuations'' means that the mercury content varies significantly from location to location. These fluctuations were caused by the geogenic structure of the soil. As it turned out, the variability caused by sample pretreatment was of the same order of magnitude as the local heterogeneity variance. The local heterogeneity variance corresponds to the sampling error variance. A significant error of sample preparation did not actually exist.

Second, the qualitative statement that sample pretreatment influenced the mercury content determined by laboratory measurement was quantified by the concept of the probable systematic error of pretreatment. Following this concept, the difference between the mean mercury content of the pretreated sample and the mean value of the respective original sample material describes the systematic error which is made if the original soil material is not available, but only material handled by a certain method can be investigated. For example, if storing the soil material in a plastic bag for at least two weeks, a probable relative systematic error of up to 40% at a confidence probability of 95% must be taken into account. The concrete results obtained cannot be immediately transferred to other objects, but they may serve as a basis for developing regulations for the handling of soil samples containing volatile compounds and for introducing controlling instruments.

ACKNOWLEDGMENTS

The geostatistical calculations reported here were carried out by M. Herbst using the Windows-based commercial computer program ''Surfer'', which is frequently used for geostatistical applications. The author wishes to thank him for providing the calculations and for helpful discussions regarding the interpretation of the results.

The list of analytical chemistry methods used for the investigation of wastes was compiled by K. Volke. He also compiled the German, European, American and International standards for this field as well as for the determination of pollutants in soils and elutriates. The author wishes to thank him for his careful work and for some useful advice.

LIST OF SYMBOLS

a	Range, Correlation Length, Minimum Distance Between Uncorrelated Data
b_l	Parameter of a Linear Variogram Model Function
C	Partial Sill of a Variogram Model
C_e, a_e	Parameters of an Exponential Variogram Model Function
cov	Covariance Operator of Two Random Variables
C_Y	Covariance Function
C_0	Nugget Effect Obtained by a Variogram Model Function
D^2	Variance Operator of a Random Variable
D^2Y_t	Variance of a Random Variable Y_t
E	Operator of the Mathematical Expectation of a Random Variable
EY_t	Expectation Value of the Measuring Variable Y_t at the Point t
G	Set of all Possible Points of the Slag Heap
I_β	Probable Systematic Error at the Confidence Probability β
K	Correlation Function
m	Degree of Freedom in Statistical Comparisons
n, n_1, n_i	Number of Samples
S_n	Standard Deviation of a Measuring Variable Y, Mean Error of an Individual Value
S_n^2, S_Y^2, S_1^2	Empirical Variance Obtained by n Samples, Maximum Variance of a Variable Y, Sill
$S^2_{\overline{Y}_n}$	Variance of the Mean Obtained by n Samples
$S\left(\lvert\overline{Y}_1 - \overline{Y}_i\rvert\right)$	Standard Deviation of the Mean Value Difference $\lvert\overline{Y}_1 - \overline{Y}_i\rvert$
$t_{m;(1+\beta)/2}$	Quantile of the Order $(1+\beta)/2$ of the t-Distribution at the Degree of Freedom m
$t, t+\tau$	Points, Sampling Locations
V	Variogram Function
V_{total}	Total Variance
w_i	Weight of a Measuring Value at a Point t_i
$\overline{Y}_n$	Mean Value Obtained by n Samples
$\lvert\overline{Y}_n - \mu\rvert$	Absolute Error of the Mean $\overline{Y}_n$
$\overline{Y}(t_0)$	Mean of a Random Variable Y at the Point t_0
Y, Y_t	Random Variable, Measured Variable at a Location t
Z_{ijklm}	Random Error of Analysis
α_i	Random Effect of Global Fluctuations Within a Model of Variance Analysis
β	Confidence Probability, Confidence Level
β_{ij}	Random Effect of Local Heterogeneities Within a Model of Variance Analysis

ε_n	Probable Error of the Mean Obtained by n Samples
ε_β	Probable Systematic Error in Statistical Comparisons at the Confidence Probability β
ε_0	Maximum Admissible Error of the Mean
γ	Semivariogram Function
γ_{ijk}	Random Effect of Sample Preparation
δ_{ijkl}	Random Effect of Sample Pretreatment
λ	Lagrange Parameter in Systems of Equations with Side Conditions
μ	Expectation Value of a Random Variable, True Content, Overall Expected Value
$\tilde{\mu}_{1,\beta}$	Confidence Limit of the Mercury Content of the Unchanged Original Material
$\lvert\mu_1 - \mu_i\rvert$	Systematic Error in the Detection of the Mercury Content Caused by Handling the Soil Sample According to the ith Method of Pretreatment
$\sigma^2_{\text{analysis}}$	Variance of the Error of Instrumental Measurement, Variance of the Error of Analysis
σ^2_{global}	Variance of a Measured Variable Caused by Global Fluctuations
σ^2_{local}	Variance of a Measured Variable Caused by Local Heterogeneities of the Site
$\sigma^2_{\text{prediction}}$	Variance of Prediction (Estimation) of an Unknown Value by Kriging
$\sigma^2_{\text{preparation}}$	Variance of Sample Preparation
$\sigma^2_{\text{pretreatment}}$	Variance of Sample Pretreatment (Handling)
σ^2_{total}	Total Variance of a Measured Variable
τ	Lag of Each of Two Measuring Variables, Spatial Distance Between Sampling Points
τ_{min}	Minimal Lag of Each of Two Measured Variables in a Sampling Scheme

ABBREVIATIONS AND ACRONYMS

Infrared (IR) spectroscopy is a universal, versatile analytical technique for the structure elucidation and quantification of a large variety of organic, inorganic and biological samples. The technique is based on the measurement of IR radiation, absorbed or emitted by a sample, as a function of the wavelength in the region 2.5–100 μm, or 4000–100 cm^{-1} in wavenumbers. The absorption or emission of IR radiation is related to discrete vibrational and rotational transitions in a molecule and, therefore, represents structural information. The analytical value of IR spectroscopy is based on the fact that the IR bands occur at more or less localized positions in the spectrum which are correlated to the presence of characteristic structural features of the sample under study. This similarity and transferability of spectral characteristics and the corresponding structural features, makes IR a powerful tool for functional group analysis. On the other hand vibrations, and thus the exact peak positions, are sensitive to the local environment which also makes IR spectra unique molecular fingerprints, highly suited for the unambiguous identification of a sample by comparison with reference spectra. Finally, IR spectroscopy obeys Beer's Law and can thus be used for quantitative purposes too.

The major advantage of IR over other spectroscopic techniques is that practically all compounds show absorption/emission and can thus be analyzed both quantitatively and qualitatively. Besides, IR spectroscopy is nondestructive and admits in situ and remote measurement of almost any sample, irrespective the physical state and without elaborate preparations. A broad variety of advanced accessories and technologies, such as IR microscopy, optical fibers, remote sensing, reflection and emission equipment and the combination with gas chromatography (GC), liquid chromatography (LC) and supercritical fluid chromatography (SFC) sampling and measurement techniques are available to tackle a diversity of problems. The absolute sensitivity is about 50–500 picograms, which is sufficient to solve many problems in trace analysis.

IR spectroscopy is used in a broad range of environmental applications. The technique is a viable tool in remote measurements of gases, liquids and solids and as a fast and reliable method for the characterization and indicative structure classification of a wide variety of samples. Besides, IR is widely applied for identification purposes either to confirm results of other techniques or for reasons of quality assurance (QA).

1 INTRODUCTION

The identification of molecular structures and the determination of their concentration in the sample is an essential part of environmental analysis. Among other selective techniques such as ultraviolet (UV), fluorescence, atomic emission and mass spectrometry, IR spectroscopy has gained wide acceptance as a viable technique for this purpose. The principle of IR spectroscopy is the measurement of the amount of IR radiation absorbed or emitted by a sample as a function of the wavelength. The wavelength of IR ranges from about 0.8 to 100 μm (12 500–100 cm^{-1} in wavenumbers) and is divided into a near-infrared (NIR) (12 000–4000 cm^{-1}) and a mid-IR (mid-infrared) (4000–100 cm^{-1}) part. This

Encyclopedia of Analytical Chemistry

chapter deals with the spectroscopy related to the mid-IR radiation. NIR spectrometry is discussed in the article **Liquid Chromatography/Infrared Spectroscopy** in this encyclopedia.

The absorption or emission of IR photons is related to rotational and vibrational transitions in a molecule and therefore represents structural information. The corresponding IR bands occur at discrete frequencies in the IR spectrum and this relation between the molecular structure of a sample and the IR spectrum is the most important analytical value of IR spectroscopy.

The potential of IR spectroscopy in the elucidation of molecular structures is very high. The number of fundamental vibrations in a molecule of N free-moving atoms is $3N - 6$. In principle, each vibration may give rise to an absorption or emission band but in practice the number is smaller as vibrations may be inactive as result of symmetry and degeneracy. On the other hand, much more than $3N - 6$ absorption bands may be present in the spectra of vapor-phase molecules as result of rotational transitions. Besides, vibrations and rotations are sensitive to a number of physical parameters, such as temperature and pressure, and to intra- and intermolecular interactions. The large number of vibrations and rotations, and the diversity of variables affecting these, make IR spectra unique molecular fingerprints, highly suited for the identification of a sample by comparison with reference spectra.

Valuable structural information can also be derived from the interpretation of spectra, e.g. in case a matching reference spectrum is absent. Contrary to identification, based on the discriminative properties of the spectrum, interpretation relates to the similarity and transferability of spectral characteristics and the corresponding structural features of molecules, i.e. functional groups. For that reason IR spectroscopy is also a useful technique for the characterization and structural classification of samples. However, as result of the large number of variables affecting a spectrum, it is extremely difficult to arrive at a complete molecular structure from a single spectrum without additional knowledge.

Finally, IR spectroscopy is an absorption technique obeying Beer's Law. It can thus be used for quantitative purposes too. A drawback compared to, for instance, UV, visible and fluorescence spectrometry is the small extinction coefficient of IR absorption bands resulting in relatively poor detection limits. Nevertheless, the current absolute limit of detection of about 10–50 picograms, is sufficient to solve many problems in environmental trace analysis.

The major advantage of IR over other techniques is that, apart from homonuclear diatomic molecules such as H_2, N_2 and O_2, all compounds show IR absorbance and can thus be analyzed qualitatively as well as quantitatively. Besides, IR is a nondestructive, noncontact technique, offering the possibilities to perform in situ and remote measurements. From this practical point of view, IR is probably the most versatile of all analytical techniques, as a spectrum can be recorded of almost any sample, irrespective of the physical state and without elaborate preparations within tenths of a second. This versatility has made IR spectroscopy a valuable analytical tool in a variety of environmental applications.

2 HISTORY

Since the development of IR spectroscopy in the early 1940s the instrumentation and environmental applications have developed through a number of stages. The first generation IR spectrometers were single-beam instruments with alkali halide prisms as the dispersive element. The sensitivity and the resolution of these instruments were poor, limiting the applications to functional group analysis and indicative quantification of milligrams of material.

In the 1960s, the instruments became double-beam, and Echelette gratings, combined with optical filters for order separation, replaced the prisms. As a consequence, the optical resolution and the stability and sensitivity of IR spectrometers were considerably enhanced and the detection limits extended to micrograms. A further development, the coupling to chromatographic techniques, via stopped-flow and flow-through cells, led to new applications, particularly in the structure elucidation of constituents in complex matrices.

A further positive impulse was given by the incorporation of computers into the IR spectrometers. Advanced data acquisition and manipulation techniques such as spectrum subtraction, programmes to search in large libraries of digitized spectra, and chemometrical methods were brought to the bench of IR spectroscopists.

Finally, the introduction of the Fourier transform (FT) principle in IR spectrometers in the 1970s dramatically improved the possibilities of IR spectrometry in a wide range of analytical problems. The high scanning speed and sensitivity of Fourier transform/infrared (FT/IR), combined with extended computer facilities for data manipulation and the development of a series of advanced accessories and technologies, such as IR microscopy, high resolution interferometers ($>0.001\,cm^{-1}$), tunable lasers, specific detectors, reflection and emission equipment and the construction of mobile and portable instruments, have brought IR to its current state of versatility and popularity.

3 SAMPLING AND MEASUREMENT TECHNIQUES

As result of the unique versatility of IR spectrometry a broad variety of sampling and measurement techniques are available to tackle a diversity of problems. The development of several of these methods originate from an environmental demand. An illustrative example is the IR remote sensing technique for the qualitative and quantitative in situ determination of gases.[1] The need to study emissions and chemical processes of greenhouse gases largely contributed to the development of this open-path technique to its current state of maturity. Obviously, the fact that global warming is assumed to be caused by the increasing release of exogenic IR-absorbing gases into the atmosphere, plays a role in this.

The principle of IR remote sensing is shown in Figure 1. In the passive mode, the sun is used as a light source or the spectrometer is operated as a detector to determine the IR radiation emitted by the subject of study. In the active mode the instrument operates as a classical source–detector spectrometer, recording absorption along the beam path to a flat mirror or a retroreflector and back. The IR source and the detector are either incorporated in one instrument or separated into modules.

Absorption measurement in a closed gas cell is a good alternative to carry out model studies and in case the analysis has to be performed on previously collected samples. Internal multi-reflection options offer the possibility of enlarging the effective pathlength to 1–100 m within the relatively small dimensions of a 10–30 cm gas cell. This method is particularly attractive in case extremely low detection limits are not crucial. Gas cells are used both separately as an accessory, and fixed, incorporated into a (mobile) spectrometer. An example of the latter is the commercially available mobile FT/IR spectrometer GASMET™ (Temet Instruments Ltd, Finland) as shown in Figure 2.[2]

Remote measurements of gases, liquids and solids can also be carried out with the help of optical fibers.[3] Fibers are used as a transmission wave guide to transfer the IR signal to and from a sensing probe, and as a sensing element itself. The fibers are made of materials such as chalcogenides that combine a certain physical flexibility with a high IR transparency. Optical fibers are particularly useful to carry out in situ measurements and to study compounds with possible toxic or corrosive activity. At present, distances of 5–50 m can be covered, depending on the desired wavenumber region to be scanned.

The advantages of optical fibers and solid-phase micro extraction (SPME) have been combined to a fiber optic

sensor system for the analysis of microcontaminants in aqueous samples.[4] The experimental set-up of this system is schematically depicted in Figure 3. The actual sensor consists of a silver halide fiber coated with a thin layer of polymer. Similar to SPME, the organic analytes are extracted from the water into the polymer film and scanned with a (portable) IR spectrometer after a certain equilibration time.

Conventional sampling methods such as the liquid cell and the KBr-pelleting technique, as well as more advanced methods such as diffuse reflectance infrared (DRIFT) and attenuated total reflection (ATR), are being used for the characterization and identification of samples in case the available amount is not the limiting factor. For quantitative purposes, liquid cells of variable pathlength, cell volume and window material are available.

IR microscopy is being employed for the analysis of small particles and in combination with the on- and off-line coupling to separation techniques for the determination of trace contaminants. The principle and applications of IR microscopy have been described by Messerschmidt and Harthcock.[5]

The application of IR microscopy as a detector in GC, LC and SFC has largely enhanced the sensitivity of these combined techniques. The current limit of detection is in the (sub)nanogram range which makes these hyphenated techniques useful alternatives or additives to commonly applied detectors such as flame ionization, electron-capture and mass spectrometry.

The interfacing of GC and IR is accomplished in three different ways which are all commercially available. The first one is on-line by means of a heated flow-through cell with an optical pathlength of 10–30 cm. This so called 'light pipe' interface allows continuous monitoring of the GC effluent.

The second one is off-line and comprises the trapping of the GC-separated analytes in an argon matrix on a rotating gold coated cylinder at 4K. After completion of the GC-run, the immobilized chromatogram can be scanned at any desired speed and resolution as long as the cryogenic conditions are maintained. This technique is called matrix isolation gas chromatography/infrared (GC/IR).

The third one is also a cryogenic sample storage technique and is called cryotrapping or direct deposition GC/IR. The analytes are crystallized directly on a moving IR transparent window at liquid nitrogen temperature (77K). Scanning can be carried out both on-line, a few seconds after deposition, or post-run, after completion of the GC separation.

The most important advantage of the sample storage methods is the sensitivity which is about two orders of magnitude better than that of a light-pipe instrument as result of the application of IR microscopy and the possibility of long-time signal averaging.[6]

A series of papers on the environmental applications of GC/IR have been published by Gurka et al.[7] The analytical value of multidimensional gas chromatography/infrared/mass spectrometry (GC/IR/MS) for the investigation of environmental samples has been summarized by Krock and Wilkins,[8] while the synergetic value of GC/IR in combination with other spectrometric techniques has been reviewed by Ragunathan et al.[9]

IR detection in LC and SFC is accomplished on-line by passing the effluent through a liquid flow-through cell, or off-line by elimination of the solvent prior

to detection of the deposited analytes. Flow cells for any type of mobile phase, including supercritical fluids, and solvent elimination liquid chromatography/infrared (LC/IR) interfaces can be purchased from several companies. Off-line detection is highly favorable since important parts of the spectral region may be obscured by absorption bands of the eluents. Particularly in reversed phase, the strong absorption of water is a major limiting factor not only in terms of poor spectral information but also in sensitivity as a feasible pathlength should not exceed 10–20 microns. An extensive review of the merits and limitations of on- and off-line coupled LC/IR has been reviewed by Somsen et al.[10]

4 ENVIRONMENTAL APPLICATIONS

Numerous papers on the application of IR spectrometry in environmental analysis have been published in analytical, environmental and spectroscopic journals. State-of-the-art surveys are frequently published of which the comprehensive biannual reviews of *Analytical Chemistry* on IR spectroscopy[11] and environmental analysis[12] are recommended as good starting points.

Papers on specific IR sampling and detection techniques also contain valuable information on environmental applications. Representative examples are the previously mentioned reviews on IR microscopy,[5] GC/IR[7–9] and LC/IR.[10]

The diversity in applications is extremely large. The analytes vary from organic and bio-organic molecules to polymers, inorganics and even microorganisms. Next to air, soil and water, IR analysis is employed in all sorts of matrices at concentration levels between bulk and trace. Real-time and in situ measurements are performed for dynamic studies while various on- and off-line methods are being used for characterization, classification, structure elucidation and quantitative analysis. A summary of the IR spectroscopic applications is presented in Table 1. A selection of the most relevant and illustrative applications is described into more detail in the following sections.

4.1 Indoor Air

The concern for good quality of indoor air has urged the development of techniques that are able to monitor the presence and release of harmful gases. Not only in the laboratory and industrial environment but also in, for instance cleaning and printing shops and during painting, relatively high concentrations of volatile organic compounds (VOCs) may be released. In principle, IR spectrometry is an attractive technique for the screening and monitoring of VOCs in the gas phase. All compounds show IR absorption and can thus be determined, while measurements can be performed remotely and continuously without any sampling. The sensitivity of IR is in the low ppm range, which is relatively low compared to some other techniques but sufficiently high for many applications. Therefore, several systems to monitor emissions of VOCs are based on IR detection.

Three types of IR–gas measurement systems can be distinguished:

1. low cost non-scanning detectors that are specifically used to determine the presence of one or two target-components;
2. portable instruments with filters or an interferometer for wavelength selection;[2]
3. remote open-path IR spectrometers.[13]

An instrument, specially designed to monitor indoor air concentrations, is the Infrared Gas Cloud (IGC) scanner developed by ter Kuile et al.[14] This apparatus is used for the selective analysis of gases in the ppm range to visualize the spatial distribution of the analyte in the workplace. Specific applications are the testing of ventilation systems and the remote detection of gas leaks.

Dispersive IR analysis of gases, released by the smoking of cigarettes, proves to be a better method for quantification than most other spectrometric techniques. The yield for carbon monoxide, hydrogen cyanide and nitric oxide turns out to be about 45% higher when detected with IR.[15]

In case direct IR measurement is hampered, for instance as result of weak absorbing properties of the analyte, indirect detection after conversion into a stronger absorbing compound is a good alternative. An example is the analysis of H_2S and O_2 which can be detected at much lower concentrations after oxidation to SO_2 and ozone respectively, by UV irradiation over a certain period of time.[16]

Preconcentration techniques, occasionally combined with a derivatization or modification, are used as well. Fillipi [17] for instance, developed a purge and trap method combined with a chemical reduction step prior to GC/IR and atomic absorption spectrometry (AAS) to determine methyl and dimethyl mercury in air at a 50 pg level.

4.2 Atmosphere and Stratosphere

The detection of exogenic and endogenic gases in the outdoor atmosphere relies to a large extent on the same methods as used for the analysis of indoor air. Similar specific single-compound detectors are used for continuous monitoring or occasional field measurements to determine and quantify a selection of predefined harmful gases and VOCs at, for example, industrial

Table 1 Applications of infrared spectroscopy in environmental analysis

Matrix type	Aim	Methods	Analytes
Ambient atmosphere	Structure elucidation, quantification, monitoring, screening, mapping, gas release	Nonscanning IR sensors, gas cells, active remote sensing, portable instruments	CFCs, VOCs, BTEX, PAHs, nitro-PAHs CO_x, NO_x, HCN, H_2S, O_2, Hg-alkanes
Stratosphere	Structure elucidation, quantification, monitoring, local and global environment, greenhouse effects, volcanic emission studies, biomass burning	Active and passive remote sensing, multipass gas cells, GC/IR mobile and airborne spectrometers	CFCs, VOCs, BTEX, PAHs, CO_x, NO_x, HCN, H_2S, O_3, ClO_x, SO_x, HCl, HF, SiF_4, $ClNO_x$, H_2O, hydrocarbons, etc.
Aerosols	Structure elucidation, quantification, combustion products and processes, photooxidation, air particulate matter	Active and passive remote sensing, multipass gas cells, GC/IR, LC/IR	(Metabolites of) terpenes, pheromones, PAHs, nitro-PAHs, nitro-cresols, phenols photodissociation and oxidation products
Smoke and exhausts	Structure analysis, quantification, monitoring, motor cars, aircraft, incinerators, power plants	Active and passive remote sensing, GC/IR mobile spectrometers, multipass gas cells	PAHs, hydrocarbons, H_2O, CO_x, NO_x, SO_x, HCN, H_2S, O_2
Water	Structure elucidation, quantification, confirmation, trace analysis	SPE, SPME, LLE/GC/IR and LC/IR, SFE/IR, sparging-IR, optical fibers	CFCs, pesticides, industrial contaminants, pharmaceuticals, oils, greases, VOCs, PAHs, biomolecules (microorganisms)
Soil	Soil characterization, trace analysis, structure elucidation, quantification	Films and pellets, DRIFT, PAS, GC/IR, LC/IR, SFE/IR, optical fibers	HA and FA fractions, pesticides, inorganics, nitrates, silicates (asbestos), oils and greases, VOCs, CFCs, PAHs
Sediments	Structure elucidation, quantification, trace analysis, confirmation	GC/IR, LC/IR, thermal desorption IR, multipass gas cells, SPME/IR	Pesticides, PAHs, oils and greases
Reference materials	QC, identity control geometrical characterization	KBr, liquid film, solutions, DRIFT, reflection, GC/IR, LC/IR	Pesticides, PAHs, PCBs, PCDFs, PCDDs
Waste	Characterization, structure analysis, quantification, recycling purposes, polymer sorting	Active remote reflection, ATR, PAS	Industrial and domestic contaminants, oil, polymers, plasticizers, detergents

PAS, photo-acoustic spectrometry; QC, quality control.

sites and waste incinerators. Multi-pass gas cells and open-path equipment are applied for the detection of other, non-target analytes.[18]

Remote sensing open-path IR spectrometry has substantial advantages over the other methods. It can be used to measure absorption as well as emission and the technique is capable of covering almost infinite distances. This offers the possibility of detecting fluxes of trace gases over a much wider area than can be achieved by any other technique. For that reason, active and passive remote sensing IR are the methods of choice for monitoring gases and gaseous emissions, not only in the lower atmosphere but at any altitude and even in space.

A review on atmospheric and stratospheric research is given by Farmer.[19] Most studies focus on the detection and the quantification of a large variety of trace gases in order to monitor possible compositional changes as a result of human activities and to get insight into the underlying physical and chemical processes. Subjects of research are the fluxes and effects of fertilizers, pesticides, industrial waste contamination, energy production, etc. Analogous studies are performed on environmental burdening by compounds emitted from natural sources, such as plants, animals, volcanic activity and biomass burning. As noted before, special interest is given to the greenhouse effect and the depletion of the stratospheric ozone layer over the Arctic and Antarctic areas.

The IR spectra of gases in space and in the stratosphere exhibit extremely narrow vibrational and rotational bands as result of the very low temperature at site. In order to extract maximum information from the spectra, high-resolution facilities are essential and for that reason, measurements are preferably carried out with instruments with a data point resolution of 0.05 to 0.002 cm^{-1}. As

Figure 4 High-resolution IR spectra recorded at the Jungfraujoch observatory; (a) the HF line at 4038.9625 cm^{-1} and (b) the NO doublet around 1903 cm^{-1}. (Reproduced by permission of The Society of Photo-optical Instrumentation Engineers from L. Delbouille, 'The Role of Very High Resolution FTS in Recent Determinations of the Quantitative Composition of the Stratosphere', *Proc. SPIE-Int. Soc. Opt. Eng.*, **2089**, 32–37 (1993).)

well as molecules involved in the photodissociation of chlorofluorocarbons (CFCs), a diversity of other minor constituents such as CO, CH_4, HF, HCl, HCN, O_3, NO_2, NO, SF_6, N_2O, N_2O_5, H_2O_2, OCS and $ClONO_2$ can be determined with this type of IR-spectrometric technique.

Measurements are performed:

1. directly by air-borne spectrometers in space and aircraft or in balloons;
2. directly by ground-based remote sensing techniques;
3. indirectly by laboratory analysis of samples collected by aircraft or balloon.

In addition to these techniques, kinetic laboratory studies are undertaken to mimic atmospheric and stratospheric conditions and processes. For this type of research, pressure- and temperature-controlled gas cells are used.

Air-borne instruments are in general of special design such as the Atmospheric Trace Molecule Spectroscopy (ATMOS) instrument that is used in Space Shuttle flights. Measurements from aircraft are usually preferred to observations from balloons, since the latter are relatively expensive and limited to balloon-accessible altitudes of about 45 km. Yet it is a viable and frequently used method for direct analysis and for the validation of data obtained from other techniques.[20]

Examples of ground-based measurements are the observations at the Jungfraujoch mountain station in the Swiss Alps, where IR spectra of the global atmosphere and stratosphere have been acquired over a period of almost five decades,[21] and the measurements in the Arctic area where the column densities of several atmospheric gases have been determined during summer and winter seasons.[22] In these observations, the sun is used as the IR light source, either directly at daytime or indirectly by reflection via the moon at night. Long-term scanning is required to get sufficient signal-to-noise ratio which implies that a tracker is necessary to follow the course of the emitting object. Examples of the information obtained from such high-resolution data are depicted in Figure 4 showing the extremely narrow absorption lines of HF and NO recorded at the Jungfraujoch observatory.

4.3 Smoke Stacks and Exhaust Gases

Many studies have been dedicated to the on- and off-line measurement of smoke stacks, and flue gases released from traffic and power plants.[23] The popularity of the remote methods is rapidly growing due to the fact that it is a noncontact real-time technique. Besides, it enables the performance of multicomponent analysis in seconds.

A remote-sensing IR method to determine the constituents of the exhaust gas of a coal-fired power plant has been developed by E. Lindermeir.[24] The principle of this method is the measurement of the emission lines of released gases at medium resolution (0.5 cm^{-1}). Accurate concentrations of H_2O, CO_2, CO, NO and SO_2 in smoke stacks at heights up to 200 m were calculated from the IR spectra using special algorithms to compensate for background fluctuations.

A commercial remote sensing FT/IR instrument RSD 1000, (Remote Sensing Technologies Inc. Maryland, USA) is used by Sjödin[25] to determine the instantaneous concentrations of CO and hydrocarbons in the exhaust of motor cars. The measurements are used to select major polluters for subsequent roadside inspection. It has proven to be a useful tool to increase the efficiency of

roadside inspections to detect cars violating governmental idle test standards.

Roadside and laboratory inspections can be readily performed by flow-through and sampled gas cells as well. The portable mobile IR spectrometer GASMET™ for instance, equipped with a 1.8 m multipass gas cell, can detect a variety of exhaust gases at levels of 0.2–20 ppm.[2]

Specific spectrometers have been developed for FT/IR emission measurements of aircraft engine exhausts under active conditions. It enables the determination of emission rates of gases like NO, CO, CO_2 and H_2O with a resolution of 0.2 cm^{-1} during the flight at cruising altitudes up to 25 000 ft.[26]

A mobile air pollution search system has been developed by the Kayser–Threde Company (Munich, Germany). The system is based on a K300 double pendulum spectrometer that operates at a spectral resolution of 0.08 cm^{-1}. In the passive emission mode, the instrument can determine gas concentrations of CO, CO_2, N_2O, NO, SO_2 and HCl in smoke-stack effluents of power plants and municipal incinerators with high accuracy.[27]

4.4 Terpenes and Biogenic Aerosols

Environmental risk-assessment studies generally comprise the release of compounds of anthropogenic origin. From the viewpoint of health care, however, the emission of molecules from natural sources are of almost equal interest. The release of gases from a single volcanic eruption, for instance, can be in the order of billions of tons. Other sources that are known to have large impacts on the local or global environment are bush fires, aqueous microorganisms and emissions from terrestrial plants (terpenes) and animals (pheromones).

Terpenes, released from plants and trees, are known to be important in the formation of photochemical oxidants and secondary organic aerosols. To determine the qualitative and quantitative composition of terpene emissions and its oxidation products in the related aerosols, an IR spectroscopic method in addition to gas chromatography/mass spectrometry (GC/MS), has been developed by Schrader et al.[28] It is demonstrated that cryotrapping GC/IR supplies important complementary information for the structure elucidation of mono- and sesquiterpenes as well as other ethereal compounds, at the high picogram level.

Biogenic aerosols from photooxidation of terpenes have been analyzed by Palen et al.[29] too, using IR microscopy. The quantitative possibilities of this method are limited but valuable information can be obtained concerning the presence of compounds with oxygen-containing functional groups such as hydroxyls, ethers, ketones, aldehydes, carboxylic acids, lactones and esters.

Finally, IR spectrometry is also used to determine and characterize waterborne microorganisms in drinking water.[30]

4.5 Volcanic Emissions

Passive and active open-path IR spectrometry are the principal methods of monitoring emissions from active volcanoes. The IR spectra are primarily used to determine the identity and flux of gases released during eruption. Other information that is extracted from the IR data deals with the eruptive history of volcanoes and the effects of vulcanism on the local and global climate. A case study on this subject is given by Chaffin et al.[31] Measurements over pathlengths of 500 m to nearly 2 km have been carried out with a mobile spectrometer operating at a resolution of 0.5 cm^{-1}. Large amounts of CO_2 and SO_2 in the volcanic plume hamper the identification of compounds that absorb in the same regions as these two components; however, several other constituents such as HCl, SO_2 and SiF_4 can be determined at ppm level in very short measurement times (less than one minute is typical). As an example of the performance of these measurements, the field-recorded spectrum of HCl and the vapor-phase reference spectrum of this compound, are depicted in Figure 5.

4.6 Biomass Burning

According to Griffith,[32] the burning of biomass is a highly underestimated source of air pollution. The annual release of carbon into the atmosphere as result of wild fires and the prescribed combustion of bush, forest, savanna and agricultural waste is about 3–6 gigaton which is of the same order as the annual combustion of fossil fuels. FT/IR studies are used to determine the composition of the smoke gases in order to distinguish between the different types of biomass burning and to assess the impact of this type of process on the atmosphere. The IR analysis is performed both directly by field measurements using long-open-path spectrometers, and by laboratory studies of smoke samples that have been taken by cold trapping in canisters at the ground and at higher altitudes using light aircraft. The in situ measurements are carried out at high resolution (0.05 cm^{-1}) with a typical pathlength of 20–200 m. The samples are analyzed by matrix isolation FT/IR.

Next to the well known carbon, sulfur and nitrogen oxides, tens of other trace gases including CS_2, CSO, HCN, CH_3CN, and hydrocarbons have been identified and quantified. A spectrum, typical for a smoke sample, is shown in Figure 6.

Figure 5 Reference IR spectrum and active field spectrum of HCl from a volcanic plume. Pathlength 1875 m, resolution 0.5 cm^{-1}, scanning time 50 s. (Reproduced by permission of Wiley-VCH from C.T. Griffith, 'FT/IR, Bushfires and Atmospheric Chemistry', *Proc. SPIE-Int. Soc. Opt. Eng.*, **1575**, 59–69 (1991).)

4.7 Volatile Organic Compounds

The relevance of the determination of VOCs in the indoor and outdoor atmosphere, and the IR spectroscopic techniques that can be used for this purpose, have already been described in sections 4.1 and 4.2. Obviously, the analysis of VOCs in other matrices is of similar importance. A rapid screening method to determine and quantify VOCs in soil has been developed by Clapper et al.[33] The principle of this method is the thermal desorption of the analytes from the soil sample with subsequent analysis of the vapor in a multipass gas cell

with a pathlength of 13.2 m. The sensitivity is at microgram level.

Fiber-optic analysis is a useful alternative when direct analysis of high concentrations of organic solvents in soil is required. As shown by Ewing et al.,[34] this technique is very selective for the identification of benzene, toluene, ethylbenzenes and xylenes (BTEX) as well as for the remote detection of high concentrations of trichloroethylene.[35]

Optical-fiber sensing is also used for the analysis of chlorinated hydrocarbons in water samples. The sensitivity of the sensor is increased by application of a polymer coating on the fiber surface. This type of analyte enrichment is analogous to the principle of SPME and enables the detection of chlorinated solvents such as tetrachloroethylene at a concentration level of 300 ppb.[36]

SPME has also been used for direct detection of VOCs in water by extraction of the organic compounds into a 130 μm thick parafilm.[37] After a certain equilibration time, the film is measured by IR transmission spectroscopy. Reproducible extraction and detection is achieved for VOCs such as benzene, toluene and chlorotoluene at concentration levels of 0.1–1 ppb.

Another technique for the determination of volatile pollutants in surface and wastewater is sparging-IR. This technique is based on the favorable partitioning of volatile and semivolatile organic molecules for the vapor phase over the liquid aqueous phase. Contaminants are forced into the vapor phase by a stream of nitrogen bubbles passing through the sample. Subsequently, the vapor is directed into a multipass gas cell for measurement of the target components. Sparging-IR is a multicomponent method with detection limits at the ppb level.[38]

4.8 Industrial Contaminants

Industrial processes and their products are a major source of environmental burdening. Production processes are generally accompanied by the emission of considerable amounts of waste chemicals, solvents and by-products. Indeed, the final products, especially chemical ones such as pesticides, pharmaceuticals, dyes, oils, plastics and paints, are obvious potential polluters. Finally, several of these compounds may give rise to the formation of metabolites and oxidation and degradation products.

Notorious examples of hazardous waste compounds are the polychlorinated benzenes (PCBs), dibenzo-*p*-dioxins (PCDDs) and dibenzofurans (PCDFs) because of their high toxicity and persistency. Other well-known industrial contaminants are VOCs, polyaromatic hydrocarbons (PAHs), phenols and (metabolites of) pesticides.

Many IR spectroscopic methods are available for the analysis of this large variety of compounds. The determination of VOCs has been discussed in the previous section. A selection of the most important other compound classes is presented in the following sections.

4.9 Pesticides

Several IR spectroscopic methods have been developed for the determination of pesticides and their metabolites in aqueous matrices. Because of the limited sensitivity of IR in relation to the required limits of detection (0.1 to 1 $\mu g\,L^{-1}$ typical), the methods usually comprise a pretreatment such as liquid–liquid extraction (LLE), solid-phase extraction (SPE), thermal desorption and derivatization.

The potentials of GC/IR for the determination of pesticides have been summarized by Kalasinsky.[39] Recent work on the combined GC/IR and GC/MS analysis of pesticides in surface and groundwaters from different locations in Lithuania has been carried out by Ellington et al.[40] Organic constituents were extracted from the water samples by SPE on cartridges. Subsequently, the cartridges were transported to the laboratory, eluted by an organic solvent and injected on the GC. As well as triazines and Alachlor, several chlorinated and aromatic carboxylic acids were determined.

A similar method for the analysis of microcontaminants in tap and surface water has been developed by Hankemeier et al.[41] After SPE extraction of 20 mL samples of water at site, the SPE cartridges are dried and brought to the lab. Next, the cartridges are desorbed on-line into the GC with 100 μL of ethylacetate using on-column large-volume injection interfacing. The IR detection is performed with a cryogenic sample storage GC/IR instrument. As can be seen from Figure 7(a), the Gram–Schmidt GC/IR chromatogram, reflecting the total IR absorption in the range 4000–6000 cm^{-1} as a function of time, permits detection and identification of all eluting components. Functional group GC/IR chromatograms (Figure 7b), show elution of compounds that absorb in a preselected wavenumber region and can be used to monitor the presence of compounds with a specific structural element.

A variety of pollutants have been identified at 0.1 to 1 ppb level, the current alert and alarm levels for micropollutants. As an example of the performance of this system, the IR spectra of the pesticides Sulfotep and Diazinon, extracted from the chromatograms recorded from 1 ppb in Figure 7, are shown in Figure 8.

The utility of solvent elimination LC/IR for the determination of pesticides in aqueous matrices has been studied extensively by Somsen et al.[42–44] Three different methods have been investigated for application to reversed-phase separations. The first method is an on-line post-column extraction of the analytes

Figure 7 Gram–Schmidt GC/IR chromatogram (a) and functional group chromatogram of the region 1580–1520 cm^{-1} (b) obtained from on-line desorption of an SPE cartridge sampled with 20 mL tap water spiked at 1 $\mu g L^{-1}$. Brinkman, 'Recent Improvements in Environmental Trace Analysis by GC/IR and LC/IR', 97–103 (1997) by permission of Elsevier Science Ltd.)

from the buffered aqueous mobile phase into the more volatile dichloromethane to improve the performance of the spray-jet LC/IR interface.[42] This technique allows identification of phenylureas and quinones at a level of 50 $\mu g L^{-1}$. Improvement has been achieved by incorporation of a trace enrichment step using on-line SPE. With this method triazines and phenylurea herbicides can be identified at the alert level of 1 $\mu g L^{-1}$. The quality of the spectra obtained from the LC/IR analysis of a 100 mL sample of river Meuse water, spiked at 2 $\mu g L^{-1}$, is shown in Figure 9. For 20 mL injections, the analyte recovery is about 90% which indicates that this method can be used not only qualitatively but also for quantitative purposes.[43]

On-line trace enrichment combined with capillary column switching LC has proven to be a useful alternative for reversed-phase LC/IR when gradient elution separation is required. Post-column extraction cannot be applied because of the continuously changing composition of the mobile phase. However, these fluctuations are masked by addition of an excess of a volatile make-up liquid. The limit of identification of this method is about 20 $\mu g L^{-1}$ for triazines.[44]

Optical-fiber sensing is suited to the analysis of high concentrations of chlorinated hydrocarbons and pesticides in water samples. Analogous to SPME, analyte enrichment is accomplished by a thin polymer film on the fiber surface. The detection limit is about 2 ppm for the pesticides Alachlor and Atrazine.[45]

Finally, the same method of thermal desorption with subsequent measurement of the vapor phase, as applied for the determination of VOCs in soil, is applied for the determination of (semi)volatile pesticides when present in high concentrations.[33]

Figure 9 IR spectra of the triazines (a) Simazine, (b) Atrazine, (c) Sebutylazine, (d) Propazine and (e) Terbutylazine detected in river water by SPE on-line trace enrichment LC/IR analysis. Water sample: 100 mL, concentration level 2 μg L^{-1}. (Reproduced from *J. Chromatogr. A*, **756**, G.W. Somsen, I. Jagt, C. Gooijer, N.H. Velthorst, U.A.Th. Brinkman, T. Visser, 'Identification of Herbicides in River Water Using On-line Trace Enrichment Combined with Column Liquid Chromatography-Fourier-transform Infrared Spectroscopy', 145–157 (1996) by permission of Elsevier Science Ltd.)

4.10 Phenols

Phenols and, particularly, nitrated and chlorinated phenols are an important class of contaminants in aqueous matrices. The compounds are released by the chemical industry as by-products, but are also formed as result of degradation of insecticides and herbicides. As result of exposure to UV radiation from the sun, oxidation and isomerization of phenols easily occurs which implies that a large number of nitro- and chlorophenol isomers is found in air, particulate matter, aerosols, wastewater effluents, surface water and groundwater. Several of these phenols are considered as high-priority pollutants and for that reason unequivocal identification is demanded.

Since IR spectroscopy is extremely powerful in the differentiation between isomers, IR spectroscopic methods have been used for this purpose on several occasions. Vredenbregt et al.,[46] for example, applied cryotrapping GC/IR in addition to GC/MS, to distinguish between the ten molecular isomers of chloronitrophenol in surface water. Despite the absence of several reference standards, all isomers have been identified by interpretation of the complementary IR and MS data. The same sample storage GC/IR technique combined with GC/MS was used by Rodriguez et al.[47] to identify structural isomers of (poly)chlorinated phenol. After acetylation and preconcentration on graphitized carbon cartridges, 17 isomers have been identified.

Childers et al.[48] employed matrix isolation GC/IR for the characterization of nitrocresols in air sample extracts. These products are formed by photooxidation of NO_x and toluene in the atmosphere. A number of specific isomers have been identified by comparison with the GC/IR spectra of nitrocresol standards.

4.11 Polyaromatic Hydrocarbons

PAHs and their nitro derivatives are well established environmental contaminants which are invariably generated during combustion processes of fossil fuels. Unambiguous identification of PAHs and nitro-PAHs is important as the mutagenity and carcinogenity among these molecules may differ considerably. The identification and structure elucidation relies primarily on GC/MS. However, especially in the absence of reference compounds, MS is insufficiently specific to distinguish between the relatively large number of isomers. GC/IR is a useful method to discriminate between PAH congeners that are difficult to distinguish by other methods. The relevance of such analysis has been demonstrated by Childers et al.[49] and Kalasinsky et al.[50] in methods for detecting and identifying PAHs and nitro-PAHs in urban air particulate matter.

Other applications of GC/IR for the analysis of PAHs are the characterization of aromatic isomers in marine sediments from mildly polluted sites in the Arabian Gulf area[51] to endorse and confirm the results from GC/MS analysis and the confirmational analysis of PAHs in soil extracts in addition to a standard high-pressure liquid chromatography/ultraviolet (HPLC/UV)/fluorescence procedure.[52]

Raynor et al.[53] demonstrated that PAHs can also be determined adequately by capillary supercritical fluid extraction (SFE) combined with off-line FT/IR microspectrometry. Several PAHs have been identified in coal tar pitch samples after evaporation of the supercritical eluent and deposition of the separated analytes on a KBr disc.

Among the PAHs, the nonalterant cyclopentafused PAHs represent a unique class, being responsible for most of the genotoxicity of PAHs exhausts. Hence, their identification and the elucidation of their build-up mechanism is of major relevance. GC/IR has been used in addition to GC/MS for the identification of these PAHs and their intermediate PAHs. A cryogenic sample storage GC/IR interface has been applied to obtain sufficient sensitivity for subnanogram detection. Experiments have been carried out on standard compounds and on samples generated by in situ pyrolysis ($T = 600–1100\,^{\circ}C$) of ethynyl PAHs as model compounds for mimicking combustion processes. Conclusions from GC/MS have been confirmed and, additionally, the molecular structures of previously unidentified components have been elucidated.[54]

4.12 Dioxins, Dibenzofurans and Polychlorinated Biphenyls

PCDDs, PCDFs and PCBs are subject to considerable environmental interest due to the combination of their high toxicity and persistency. The three compound classes count 75, 135 and 209 congeners respectively, differing over six orders of magnitude in toxicity. It follows that highly sensitive univocal identification is required for these substances. For that reason, high-resolution GC/MS is the method of choice for this type of analysis.

Occasionally, however, additional IR spectrometric information is necessary to distinguish between the large number of possible molecular isomers, either for confirmational purposes in addition to GC/MS analysis, or for the identification of compounds that are to be used as analytical standards. As a consequence, many IR studies have been dedicated to the analysis of PCDDs, PCDFs and PCBs. Also, IR data are used to obtain information on the relationship between the toxicity and the geometrical structure of the molecules. Grainger and co-workers,[55,56] for instance, demonstrated that the IR vapor-phase spectra point to a near planar geometry for the highly toxic laterally substituted isomers, and a more tetrahedral type of geometry for the less toxic isomers in which the aromatic rings have lower electron withdrawing capacity. These conclusions are consistent with the data obtained from X-ray crystallography.

The importance of the identity conformation of standard materials for reference purposes has also been commonly acknowledged. Examples are the characterization of PCBs[57,58] and chlorinated and brominated dibenzodioxins and dibenzofuranes,[59] by matrix-isolation GC/IR, and the recording of the GC/IR reference spectra of all 209 individual PCB congeners.[60] The discriminative properties of IR spectrometry for this type of analyte are well illustrated by the spectra of 5 congeners of chlorinated and brominated dibenzodioxins in Figure 10.

Applications of IR spectrometry to the analysis of PCDDs, PCDFs and PCBs in real-life samples are scarce and restricted to samples with high concentrations. A recently published example is the GC/IR analysis of extracts of fly ash from a municipal waste incinerator to confirm the results from GC/MS.[61] PCDD- and PCDF-congeners have been identified unambiguously at high picogram level as result of the complementary information from both techniques.

Figure 10 Matrix isolation GC/IR spectra of 2,3,7,8-substituted dibenzo-*p*-dioxins. (a) 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin, (b) 2-bromo-3,7,8-trichloro-dibenzo-*p*-dioxin, (c) 2,3-dibromo-7,8-dichloro-dibenzo-*p*-dioxin and (d) 2,3,7,8-tetrabromo-dibenzo-*p*-dioxin. Barbour, 'Characterization of Brominated and Bromo/chloro Dibenzo-*p*-dioxins and Dibenzofurans by Gas Chromatography/Matrix Isolation-Infrared Spectrometry', 1285–1290 (1992) by permission of Elsevier Science Ltd.)

4.13 Oils and Greases

For many years, the quantitative determination of mineral oil in water, soil and sediment samples by IR spectrometry has been a widely applied standard protocol for environmental and QC. The methods are based on the extraction of the hydrocarbons by an apolar solvent, followed by elimination of possibly co-extracted polar substances by means of Florisil, and subsequent measurement of the absorption maxima of the C–H

Figure 11 Characteristic absorption pattern of mineral oil extracted from a soil sample.

stretching bands in the extract. The limit of detection is in the order of 0.05 to 1 mg L^{-1}, depending on the extraction solvent and the pathlength of the liquid cell (1–5 cm typical). An example of the usual absorption pattern of a mineral oil is shown in Figure 11.

Up till now the extraction, prescribed in the protocols, has been carried out with halogenated hydrocarbons such as carbon tetrachloride and freon-113 as these solvents are IR transparent in the relevant wavenumber region 3200–2700 cm^{-1}. However, as result of the ozone-depleting effects of chlorinated fluorocarbons (CFCs), research is going on to alternative extraction methods without the use of these solvents. Several excellent alternatives for extraction and preconcentration have been proposed, such as adsorption filtration,[62] SPE, SFE, microwave-assisted extraction (MAE) and LLE in strongly reduced liquid volumes or in nonhalogenated solvents.[63] In parallel, ATR and DRIFT have been tested as alternative methods for the extinction measurement of the alkyl bands after evaporation of the solvent. The performances of several of the new methods are comparable or even better than the conventional ones with detection limits in the order of 0.005 ppb and a recovery of 90%.

Another alternative for the relatively elaborate extraction methods is direct screening by optical-fiber sensing. This in situ method is very fast but can only be applied for highly contaminated wet soils.[64]

4.14 Soil Characterization

IR spectrometry is commonly applied for the characterization of soil humic acid (HA) and fulvic acid (FA) fractions. HA and FA substances are complex organic macromolecules formed by degradation of biotic material such as cellulose, lignins, peptides, saccharides, etc. The large variety in the precursor structure combined with the many different parameters affecting the degradation process, results in an enormous diversity of the chemical and physical properties of humic substances. These properties play an important role in environmental analysis of xenobiotic compounds and for that reason the characterization is an important task. IR spectroscopy is a useful method for this purpose, particularly in the determination of the oxygen contents of humic and FAs. Information on the oxygen contents of both untreated as well as fractionized HAs and FAs can be derived from the position and the band pattern of the OH stretching bands around 3300 cm^{-1}, the strong absorbing symmetric and asymmetric C(=O)−O− stretching vibrations at 1600 and 1400 cm^{-1} and the −C−O−C bands in the region 1200–1000 cm^{-1}, which are correlated to the presence of hydroxylic, carboxylic and ether groups, respectively.[65,66] Examples of the IR spectra of peat HA fractions are given in Figure 12.

An IR method, closely related to characterization of HA fractions, is the analysis of residual fractions that remain after microbiological degradation of contaminated soil.[67] In this application, IR spectrometry is used to determine oxidation products of the original contaminants.

Another way to classify humic substances is by pyrolysis GC/IR.[68] With this technique, HA and FA fractions are characterized by the identity of the different pyrolysis products such as acids, lactones, alcohols and phenols, and their relative abundance.

Gessa, 'IR, Raman and Nuclear Magnetic Resonance (^{1}H, ^{13}C and ^{31}P) Spectroscopy in the Study of Fractions of Peat HAs', *Appl. Spectrosc.*, **50**, 1165–1174 (1996).)

4.15 Inorganics and Asbestos

Occasionally, IR is used to determine the quantity of specific inorganics such as minerals and nitrates by means of conventional KBr measurements, DRIFT or photoacoustic IR.

A specific application is the analysis of asbestos (hydrated silica fibers) which is of concern owing to its assumed lung cancer causing properties. Although microscopy is usually the principal method for the determination of the type of asbestos, IR is often used for additional identification and confirmation. As demonstrated by Lang et al.,[69] IR can be used for the quantification as well. A method has been developed to quantify asbestos down to 0.01% by weight using an ashing technique to eliminate the cellulose matrix prior to absorption measurement.

4.16 Polymer Characterization

For obvious reasons, the recycling of sorted plastics has a number of advantages over unsorted regeneration. IR is highly suited for the identification of polymers and for that reason the application of IR for polymer recognition in waste industry is logical. At present several methods for automated plastic-waste identification are being employed. All applications are based on a fast, remote recognition of polymers in a stream of waste.[70]

Examples of IR classification of (co)polymers for recycling purposes are found in the automobile industry, the regeneration of electronic equipment,[71] the identification of waste carpet materials and in sorting plastics from municipal solid waste.[72] The latter combines the spectral IR and NIR information with additional geometric information by means of a focal-plane IR imaging system.

4.17 Quality Assurance

As already noted, IR spectrometry is commonly used for confirmational purposes and identity control of analytical standards prior to performing qualitative and quantitative analysis. Confirmational analysis is important since unambiguous identification of substances with suspected toxic properties is subject to stringent forensic and regulatory requirements. Identity control is relevant as the growing importance of good laboratory practice (GLP) has increased the prescription of IR for the QC of analytical standards.

In general, the analytical procedure and the criterion for confirmation are described into detail in a Standard Operating Procedure (SOP) in accordance with requirements as proposed by the International Organization for Standardization (ISO). Several criteria and algorithms have been developed to express the similarity between two spectra in a reliable and useful number. Nowadays, the software of virtually all IR instruments offers this possibility while also less stringent peak-matching requirements[73] as well as criteria based on neural networks,[74] have been proposed as decisive criteria to confirm the identity of a standard or an analyte.

4.18 Chemometrics and Model Studies

Nowadays, chemometrics plays a very important role in IR spectroscopy. The fact that FT/IR instruments are inherently equipped with fast processors and large storage capacity for data acquisition, processing and manipulation has made it considerably easier to use chemometric techniques like discriminant analysis (DA), principal component analysis (PCA), partial least squares (PLS) regression and artificial neural networks (ANN). On the other hand, the need for application of these techniques has been urged by two developments. Firstly, the current instrumentation produces increasing amounts of spectral data in shorter time and spectra are currently obtained within a tenth of a second. Secondly, the development of two- and three-dimensional mapping facilities and the coupling to GC and LC, has manifolded the number of spectra to be handled. In order to facilitate or even admit the interpretation of this enormous amount of information, chemometrics are practically indispensable and have, therefore, become common sense in modern IR spectroscopy. Data reduction and data storage methods are applied to reduce the large amount of data to feasible proportions in terms of desk and memory space while multivariate calibration techniques have been incorporated into the standard instrument software for data manipulation and simplification of the interpretation. Besides, expert systems have been developed to enable unskilled spectroscopists to take advantage of unknown possibilities of IR spectrometry. Examples are the chemometrical systems that are used to assist in the structure elucidation of unknowns.[75,76]

Model studies are a valuable method to predict the course of processes when only a limited number of data is available or in case extended studies cannot be performed for practical reasons. Particularly, in large-scale processes such as environmental exposure and risk assessment, computerized models are indispensable. Several models, partly or fully based on IR spectroscopic data, are currently used for this purpose. An important additional advantage of IR spectrometry is the possibility to perform real-time and in situ measurements which enables the development and the validation of a model not only in the laboratory but also in real-life situations.

A good example are the computerized models that are used in studies of the greenhouse effect. These models take into account a variety of parameters such as the atmospheric and earth temperature, cloud cover, geographic coordinates, weather conditions and the composition of the atmosphere as a function of the altitude. Obviously, IR remote sensing is very well suited to provide the required qualitative and quantitative data of greenhouse and other gases. Moreover, the same technique can be used for the validation by monitoring the actual atmospheric composition and (photo)chemical processes.

Specific examples of model studies based on IR data are of those of Collete[77] and Nelson et al.[78] The first one applied PLS modeling of IR spectral data, to predict chemical and physical constants and distribution coefficients of a number of pollutants in order to estimate their environmental fate. The second one carried out a model study to determine the parameters that affect the formation of toxic constituents during incineration of wastes.

5 CURRENT POSITION AND FUTURE DEVELOPMENTS

At present, IR spectroscopy is a viable method for many applications in environmental analysis. The merits of the technique lie in its versatility and in the unique fingerprinting properties of the spectra. The first makes

IR the principal method for remote sensing and in situ measurements as illustrated by the applications in atmospheric studies and the classification of polymers. The second makes it, in principle, the method of choice for unambiguous identification. In trace analysis, however, mass spectrometry is superior in sensitivity and ease of operation and for that reason the role of IR is mainly restricted to QC and confirmational purposes.

Future applications should be seen in relation to developments in hard and software. The recent introduction of diode array detection in IR spectrometry is a good example of the ongoing attempts at innovation. Further development of this type of detection can be expected. Research will also focus on improvement of the sensitivity by means of dedicated detectors and tunable IR laser technology. At short notice, the ongoing demand for fast and robust methods will lead to the further development and optimization of dedicated, low-cost sensor type of instruments, particularly suited for routine and field measurements. As such, the growing interest in NIR spectrometry for routine tasks, currently performed with mid-IR techniques, will most likely continue.

Finally, it should be noted that the improvement of IR technology will be attended by similar developments of other analytical techniques. For that reason, the choice for application of an IR spectroscopic method has always to be judged in relation to the potential of alternatives which includes economical and practical considerations such as the availability of instrumentation and expertise.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectrometry
ANN	Artificial Neural Networks
ATMOS	Atmospheric Trace Molecule Spectroscopy
ATR	Attenuated Total Reflection
BTEX	Benzene, Toluene, Ethylbenzenes, and Xylenes
CFC	Chlorinated Fluorocarbon
CFC	Chlorofluorocarbon
DA	Discriminant Analysis
DRIFT	Diffuse Reflectance Infrared
FA	Fulvic Acid
FT	Fourier Transform
FT/IR	Fourier Transform/Infrared
GC	Gas Chromatography
GC/IR	Gas Chromatography/Infrared
GC/IR/MS	Gas Chromatography/Infrared/Mass Spectrometry
GC/MS	Gas Chromatography/Mass Spectrometry
GLP	Good Laboratory Practice
HA	Humic Acid
HPLC/UV	High-pressure Liquid Chromatography/Ultraviolet
IGC	Infrared Gas Cloud
IR	Infrared
ISO	International Organization for Standardization
LC	Liquid Chromatography
LC/IR	Liquid Chromatography/Infrared
LLE	Liquid–Liquid Extraction
MAE	Microwave-assisted Extraction
mid-IR	Mid-infrared
NIR	Near-infrared
PAH	Polyaromatic Hydrocarbon
PAS	Photo-acoustic Spectrometry
PCA	Principal Component Analysis
PCB	Polychlorinated Benzene
PCDD	Dibenzo-*p*-dioxin
PCDF	Dibenzofuran
PLS	Partial Least Squares
QA	Quality Assurance
QC	Quality Control
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
SOP	Standard Operating Procedure
SPE	Solid Phase Extraction
SPME	Solid Phase Micro Extraction
UV	Ultraviolet
VOC	Volatile Organic Compound

Capillary electrophoresis (CE) is a very useful technique which involves the separation of charged species (molecules) on the basis of their movement under the influence of an applied electric field in a capillary format. CE has been developed into rapid, highly effective techniques with extremely high separation power (10^5–10^7 theoretical plates) and high mass sensitivity (femtomole to zeptomole amounts of substances in nanoliter to picoliter sample volumes) with high potential for separation in the analysis of environmental sample. CE has been compared with ion chromatography (IC) in the inorganic analysis of environmental samples since inorganic ions are usually separated by IC with suppressed conductivity detection. The advantages of CE compared to IC are speed, resolution, and the lack of a need for gradient elution. Operating costs are considerably lower, since ion-exchange columns are usually expensive. In application, however, limitations imposed by the lack of detection sensitivity complicate the technique's use and impede its wide acceptance. However, as instrumental development continues (especially in detection mode and other techniques for manipulating sensitivity), this limitation will most likely be overcome and a diversity of inorganic species in real samples has already been proved to be amenable to the analysis by CE, and more can be expected in the years ahead.

In this article, to understand how CE can be applied to separation and detection of inorganic ions of environmental sample, the basic principles underlying this technique and the operating parameters of CE for inorganic analysis of environmental samples are presented. For trace analysis of environmental samples, methods for manipulating the sensitivity and selectivity control for metal ions are discussed. Techniques such as the coupling of CE with inductively coupled plasma mass spectrometry (ICPMS) are also discussed. Specific applications in real world samples which have complex matrices as well as artificial samples or reference materials are offered to demonstrate the potential of CE in the analysis of environmental pollutants.

1 INTRODUCTION

Inorganic pollutants of environmental samples comprise a variety of metal species and small anions. Since at trace level they are usually in unknown and variable matrices as various chemical states, a sensitive and selective technique is always required for their determination.

CE is an emerging technique in this area. CE possesses many unique advantages for the analysis of environmental pollutants, which include small sample volumes, high mass sensitivity, high separation efficiency, low cost columns, easy rinsing of the column, low consumption of reagents, simple methodology, short analysis time, etc. CE, which was initially developed for the separation and determination of biopolymers such as proteins, peptides and organic compounds, has been rapidly introduced into the analysis of inorganic ions since the early 1990s and has become a promising technique for the

inorganic analysis of environmental samples. The active research in CE reflects the expectation of this method for the replacement or supplement to high-performance liquid chromatography (HPLC) or IC with suppressed conductivity detection, which is the most popular method at present in this area. However, the use of CE as a routine quantitative technique in environment analysis is still limited because of the low concentration sensitivity of CE due to the small sample volume. However, as instrumental development continues (especially in detection mode and other techniques for manipulating sensitivity), this limitation will most likely be overcome.

In order to give a better understanding of how CE can be applied to the separation and detection of inorganic ions of environmental samples, this article will present the basic principles underlying this technique and operating parameters of CE for the inorganic analysis of environmental samples. Methods for manipulating the sensitivity (important for trace analysis) and selectivity control for metal ions are also introduced. Specific applications in real world samples as well as artificial samples or reference materials will be offered to demonstrate the potential of CE in the analysis of environmental pollutants.

The basic principles and instrumentation relevant to the separation of inorganic ions and applications to environmental analysis are discussed in several books[1–6] and reviews.[7–13] There are over 100 reviews about other specific issues related to CE, such as detection technique, derivatization, mathematical modeling, etc. Among them, some reviews on environmental application are recommended to the interested reader.[7–24]

CE can be performed in various modes with differing mechanisms of separation, such as capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), micellar electrokinetic capillary chromatography (MEKC), capillary electrochromatography (CEC), capillary isoelectric focusing (CIEF) and capillary isotachophoresis (CITP). In this article, CE represents CZE with an on-line ultraviolet/visible (UV/VIS) absorbance detector unless specifically defined.

2 BASIC PRINCIPLES

2.1 Capillary Electrophoresis System and Operating Parameters

The general mechanism for CE separation is based upon differences in the mobility of solutes transported along a capillary tube by a high dc voltage. In the simple system shown in Figure 1(a), both ends of the fused silica capillary, filled with a suitable electrolyte, are immersed into two reservoirs of the same electrolyte.

Figure 1 (a) Schematic of CE system; (b) mechanism of CE.

The capillary is normally 50–100 cm long with an internal diameter of 25–100 μm. A high potential difference of 20–30 kV is applied across two platinum electrodes in the reservoirs.

The sample (several nanoliters) is injected into the capillary and the components of the sample migrate towards the negative electrode. Because the cross-section of the capillary is small, a high surface to volume ratio is achieved. This dissipates heat, generated by joule heating, to the surroundings. Convective mixing within the capillary is, therefore, not significant and band broadening is minimized, resulting in efficiencies of several hundred thousand plates.

Electroosmotic flow (EOF) of the solvent occurs in the capillary because an electric double layer is formed at the capillary surface (Figure 1b). The fused silica capillary surface has a net negative charge owing to the dissociation of the functional groups on the capillary surface. Positive ions are attracted from the buffer solution and an electrical double layer is formed at capillary surface. When an electric field is applied, mobile positive ions, present at the capillary surface, are attracted to the negative electrode, and solvent molecules are transported concurrently. A unique feature of EOF in the capillary is the flat profile of the flow, which is beneficial because it does not directly contribute to the dispersion of solute zones.

The movement of analyte ions is caused by the combination of electrophoretic mobility of the analyte ion and the EOF of the solvent. Therefore, depending on whether or not the electrophoretic mobility has a similar direction to the electroosmosis, the separation mode in CE is divided into coelectroosmotic or counterelectroosmotic modes. Within a bare fused-silica capillary, small cations which are attracted to the negative electrode migrate at a velocity greater than the EOF (coelectroosmotic flow). Conversely, anions are repelled by the cathode and migrate more slowly than the EOF (counterelectroosmotic flow). Neutral species move with the EOF and are generally unseparated unless some modification to the surface charge of the analyte is made by

the addition of a surfactant (MEKC). The direction of the EOF can be decreased or reversed to achieve reasonable analysis times for small anions. The polarity of capillary wall can be modified by the addition of EOF modifiers.

A traditional CE detector that is commercially available is the on-column UV/VIS spectrophotometer. The small capillary diameter of CE creates a thin beam path for on-column UV/VIS detection. This creates a sensitivity problem in the study of environmental samples which usually require the detection of species in trace or ultratrace levels. To overcome this problem, many detection techniques have been developed for CE. Among them laser-induced fluorescence (LIF) and amperometric detectors are commercially available.

Since most small cations and anions lack the necessary chromophore properties allowing a straightforward detection at any wavelength above 200 nm, indirect detection is often employed for the detection of ultraviolet (UV) transparent ions. A UV-absorbing co-ion (or probe co-ion) is present in the background electrolytes (BGE) and detection is accomplished as a result of displacement of the probe ion by analyte ions. Commonly used electrolytes for anion determination are chromate[25] and pyrromellitate[26] and for cation determination, 4-aminopyridine,[27] imidazole[28] and creatinine.[29]

2.2 Electrolyte Condition

For many ions, the mere combination of electrophoresis and electroosmosis does not offer a sufficient selectivity for a satisfactory resolution from other peaks in the sample mixture. It is required frequently to refine CE separations by utilizing analyte interactions with suitable components in the electrolyte. Optimization of the CE separation can be difficult due to the wide array of parameters and variables that must be controlled. However, it is worth understanding several possible factors contributing to the selectivity of CE and its trend for the separation of inorganic ions. The pH level, concentration, component of electrolyte, additives, and EOF are regarded as the most important factors. Their influence on the selectivity is quite different depending on the sample status, especially on the sample polarity.

2.2.1 pH

The pH of the separation electrolyte must be carefully selected. While cationic separations are mostly performed at pH 3–5, anionic separations are seldom carried out using an electrolyte with a pH value below 7. This fact can be attributed to the different behaviors and properties of cations and anions in aqueous solutions. Cations, especially those of transition metals and some of alkaline earth metals, readily precipitate at high pH. In addition, the electrolyte constituents for providing an indirect detection mode for cations mostly have pK_a values in the low pH range. To match the mobility of the sample cations, the pH has to be sufficiently low so that almost all the electrolyte constituents are present as cations. On the other hand, for the determination of anions, the electrolyte pH has some effect only on the anions of weak acids. In acidic conditions, serious tailing and unacceptably long migration time occurs for the anions of weak acids in coelectroosmotic mode, e.g. acetate and carbonate. The long migration time results from the effect of EOF due to the change of pH. The EOF rate increases with the pH because of a large degree of dissociation of silanol groups on the capillary wall.

2.2.2 Concentration

The concentration of carrier electrolytes affects the selectivity. In general, a longer migration time can be expected with increasing concentrations of electrolyte. This is explained by increases in separation currents and the corresponding weakening of the electric field in the capillary filled with carrier electrolytes. Sample stacking effects can be obtained at an electrolyte concentration 10–100 times higher than the sample concentration. However, a high concentration of electrolyte will give the deteriorating joule heating effect which makes bubbles inside the capillary and sometimes results in a breakdown of voltage.

2.2.3 Selection of Electrolyte Component

Depending on the detection mode and interested ions, the background electrolyte is selected. When indirect UV/VIS detection is used, the electrolyte ion must be chromophoric as discussed above. A shift from one electrolyte to another is more commonly dictated by one of the conditions of CE, prescribing the match of mobilities between analyte ions and electrolyte co-ions. When the electrolyte anion has a lower mobility than the solute anions, an asymmetrical, fronting peak may result. This is because the high mobility solute anions tends to migrate ahead of the sample zone. Conversely, when the electrolyte anion has a higher mobility than the solute anion, a tailing peak results. Distinct tailing, usually observed for most carboxylates in chromate, can be avoided by choosing a phthalate-containing electrolyte. The selectivity of the separation of low mobility anions can be modified even to the complete reversal of order of migration by switching from coelectroosmotic to the counterelectroosmotic mode by addition of EOF modifier.

2.2.4 Additives

The use of additives in CE lead to dramatic changes in separation power. Micellar, complexing reagents, EOF modifiers, and organic solvents are various types of additives that have been used to control the selectivity of the separation.

The addition of an organic solvent to the electrolyte will change migration times and selectivity. The manipulation of selectivity use of organic solvents offers these advantages due primarily to an effect on the solvation of cations and on the ion pairing of anions. The addition of organic solvents to carrier electrolytes can lead to longer migration times with increasing concentrations of a solvent and the change of migration order of anions. It is assumed that organic solvents tend to shift ion pairing equilibrium to the right for anions. For cations, the solvation effect is accomplished by the changes in charge density, since in comparison to aqueous electrolytes, polar organic solvents affect the actual size of ions via forming ion solvent dipole bonds. The mobilities of solvated cations or ion paired anions are also influenced by changes in the viscosity of water–organic mixtures. One particular advantage of organic solvents, especially with regard to ionic complexing additives, is that the ionic strength of the capillary electrolyte is not increased, which prevents possible thermal effects.[30] Among a variety of organic solvents that have been studied with regard to their suitability for CE, methanol, *N*-methylformamide, dimethylformamide, dimethyl sulfoxide and acetonitrile[31] seem to be particularly useful. More detailed information on the important properties of organic solvents for use in nonaqueous CE separations were summarized in a review.[32]

The effect of micelles, complexing reagents, and EOF modifiers will be discussed in other sections.

2.2.5 Electroosmotic Flow

The regulation of the rate of EOF is another way to enhance the separation in CE. Although the EOF does not contribute to the selectivity changes (at least for the analytes of the same charge), it has been demonstrated to be useful in manipulation of the resolution, in particular, in micellar-mediated CE systems. Since the migration velocities of small, charged ions exceed the velocity of the EOF, the coelectroosmotic separation principle is usually preferred for inorganic analysis. In uncoated capillaries, the direction of the EOF is from the anode to cathode, which means that only cations can be separated without modification of the capillary wall. The direction of the EOF has to be decreased or reversed to achieve reasonable analysis times for small anions. EOF modifiers such as cetyltrimethylammonium bromide (CTAB),[33] tetradecyltrimethylammonium bromide (TTAB),[34] or hexamethonium hydroxide (HMH)[26] have been used for this purpose.

2.3 Detection System

2.3.1 Photometric Detection

Currently, most commercially available instruments for CZE are equipped with spectrophotometric detectors, in particular UV-absorbance detectors. This detector is preferred because it offers minimal loss in separation efficiency and easy set-up. As most small cations and anions lack the necessary intrinsic chromophore properties allowing a straightforward and sensitive detection at any wavelength above 200 nm, their detection generally requires derivatization using a suitable chromophore prior to separation. Otherwise indirect UV detection should be applied. For analysis of metal ions, derivatization can be also used to enhance the selectivity. Details of the method will be presented in the following section.

As the key to the latter approach is the displacement of a highly absorbing electrolyte co-ion, a close mobility match to the analyte ions is required; otherwise asymmetrical peak shapes are generated. Commonly used electrolytes for anion determination are chromate and pyrromellitate and for cation determination, 4-aminopyridine, imidazole and creatinine. While UV/VIS absorbance detection is the most common, straightforward, means of accomplishing on-column detection for CE, achievable sensitivity is limited due to short beam pathlength. Usually the limit of detection (LOD) is below the order of 10 mM. It is not sensitive enough for environmental trace analysis. Even so, CE still has an impressive mass sensitivity, which can compete with the best HPLC system because of a very low injected sample volume. To enhance concentration sensitivity for CE, various approaches have been developed. These approaches include preconcentration by solid phase extraction (SPE), on-line preconcentration by isotachophoresis (ITP), on-column preconcentration by sample stacking, and use of detection cells with extended optical pathlength. Albin et al.[24] have presented a review in this field.

As UV detectors, photomultipliers or diode array detector (DAD) is used. Photomultiplier has a higher sensitivity than DAD while DAD offers a full spectrum. Since inorganic ions do not have a unique UV/VIS spectrum, photomultiplier is desirable since it usually gives more sensitive results.

As more sensitive optical detection methods have been pursued, fluorescence has become the most popular, as demonstrated by the numerous applications described in a recent review.[18] LIF can provide LOD several orders lower than UV absorbance. Using direct fluorescence, detection limits in the attomole to zeptomole range and

even single molecule detection has been reported for polyaromatic hydrocarbons and proteins. In the field of study of metal ions, direct fluorescence detection of complexed metal ions was accomplished by Swaile and Sepaniak. Using 8-hydroxyquinoline-5-sulfonic acid (HQS), which fluoresces only when complexed, Mg^{2+}, Ca^{2+}, and Zn^{2+} can be detected in the ppb range.[35] More commonly, indirect fluorescence detection techniques were used for analyses of metal ions, although the number of studies has been rather limited. Using a quinine sulfate electrolyte buffer system for indirect fluorescence detection and electrokinetic detection, alkali and alkaline earth metals were detected at femtomole levels. Indirect LIF detection for capillary separation was reviewed by Yeung and Kuhr.[36]

Indirect LIF detection is also possible with MEKC. The sensitivity relies upon the different quantum efficiency of the fluorescent reagent in the two phases. Generally, the quantum efficiency of the fluorescent reagents is significantly enhanced in the micellar phase, and the displacement of it from the micellar phase to aqueous phase by the analytes caused a concomitant reduction in the fluorescence signal.

Chemiluminescence (CL) detection involves the reaction of the analyte, or some species produced by the chemical or enzymatic reaction of the analytes with a CL reagent to produce light in the detection cell. The most common CL detection system utilizes the hydrogen peroxide–luminol reaction, in which the hydrogen peroxide is a by-product of a chemical enzymatic reaction of the analyte. Alternatively, a variety of metal ions catalyze the reaction of hydrogen peroxide and luminol in alkaline solution and can thus form the basis of direct[37] and indirect[38,39] CL detection. For high sensitivity detection of metal ions separated by CE, Huang et al.[37] combined the incorporation of luminol into the separation buffer with post-column mixing of the hydrogen peroxide solution immediately before passing through the detection region. They reported the best system detection limits for Co(II) (20 zmol, $5 \times 10-13$ M) while other metals gave mass detection limits ranging from 2 amol to 100 fmol. Average reported plate counts were over 400 000, indicating no compromise in separation performance due to the post-capillary mixing of CL reagents.

2.3.2 *Conductivity Detection*

In addition to detection methods based on spectrophotometric principles, CZE combined with a conductometric detector has been presented in a number of published papers.[40–48] Different detector configurations suitable for both on-column and end-column conductivity detection have been reported but only the latter technology is commercially available to date.

Compared to CE with UV detection, devices equipped with conductometric detection offer significant enhancement in performance and sensitivity especially for the analysis of low molecular mass ionic compounds. Whereas in CE with UV detection the suitability of a certain carrier electrolyte strongly depends on its UV absorptivity, low-conductivity buffers or buffers suppressible with common methods are used in the case of CE devices equipped with non-suppressed or suppressed conductivity detection respectively. In non-suppressed conductivity detection, the so-called Good's buffer components[47,48] proved to be suitable carrier electrolytes for a number of separation problems.[42–45,49,50] Because the first commercially available CE device offering the possibility of conductivity detection was introduced recently,[45] only a small number of papers dealing with the applicability of this system for the analysis of real samples has been published. Since the high sensitivity inherent to electrochemical detection (ED) does not depend on the scale of measurement, ED could become an important alternative detection mode for CE.

Conductivity detection for CE was addressed during the covered period.[51,52] A simple conductivity detector with detection limits in the nanomolar range was demonstrated.[51] Suppressed conductivity detection for CE was discussed in terms of its compatibility with various electrolyte systems.[52]

2.3.3 *Inductively Coupled Plasma Mass Spectrometry*

ICPMS has great potential usefulness owing to a very low detection limit obtainable without preconcentration and a large dynamic range. It is noted that there is no need to separate species electrophoretically that contain different elements from each other as the ICPMS detector serves to identify the metals present individually. Speciation studies are of primary interest for CE coupled with ICPMS as only ions, complexes or molecules containing the same element need to be separated. Therefore, for different element ions of similar mobilities, electrophoretic resolution will be poor but the ions will be adequately identified by the ICPMS element specific detector. The coupling of CE with ICPMS is relatively new and interface designs are still being developed and evaluated. The use of direct injection nebulization and other low flow nebulizers are, without a doubt, the way forward if electropherographic resolution is to rival that obtained with UV detection.

The coupling of CE with ICPMS for elemental analysis has been reported by several groups.[53–56] Two major challenges for the coupling of this technique need to be addressed. They have been described by Tomlinson et al.[57] The flow-rate (typically of the order of nL min^{-1}) and low sample volume of a typical CE separation is the

first potential problem, as most nebulizers for ICPMS are designed to operate at flow-rates in the mL min^{-1} range. Glass frit,[55] direct injection, oscillating capillary, ultrasonic[54] and Meinhard nebulizers[56] are suitable for such low flows. Another factor to consider is that the end of the capillary will no longer be immersed in a buffer reservoir upon coupling to ICPMS and a method of ''grounding'' the electrode must be achieved. The construction of such an interface is an important consideration so that high transport efficiency is achieved.

3 SELECTIVITY CONTROL BY COMPLEX FORMATION

The electrophoretic mobility in CE, μ_{eff}, is originally determined by the intrinsic solute parameters, effective charge to size shown in Equation (1):

$$\mu_{eff} = \frac{q_i}{6\pi\eta r_i} \quad (1)$$

where q_i is the charge of hydrated or complexed ion, r_i is its size (the hydrodynamic radius) and η is the viscosity of the electrolyte medium. In the separation of metal species such as alkaline metals, alkaline earth metals, transition metals or lanthanides, the electrophoretic mobilities of most metal ions or metal complexes are similar in magnitude since they possess nearly identical charge and size. To improve separation efficiency of metal ions in CE, altering either the effective charge or size of a metal species or both is required. This can be done by the complex formation of the sample during (on-capillary) or before electrophoresis (pre-capillary), as well as routine practice of compositional changes of the carrier electrolytes resulting in ion dissociation or change of solvation effect, etc. Therefore a distinct feature of the separations of metal ions by CE is the frequent use of ligands to form complexes with the metal ions.

Classifications of complexation reaction are based on either their place in the final analytical set-up: before (pre-capillary), or during (on-capillary) the electrophoretic separation; or the degree of metal ion complexation due to the thermodynamic stability of the metal complexes: partial or total complexation.

In the partial complexation approach, usually on-capillary reaction with weakly complexing ligands such as the variety of carboxylic and hydroxycarboxylic acids takes place. In this case, the complexation reaction should be fast and quantitative to be detected within the time of typical CE run, and the complexing agent should be stable. Separation selectivity is most easily manipulated in this mode coupled with indirect photometric detection. The simultaneous separations of the greatest number of metal ions have been achieved using this approach.

On the other hand, in the total complex approach, metal ions are completely transformed into moderate to strong complexes usually in pre-capillary mode or rarely on-capillary mode. Adapting pre-capillary complexations, there are some advantages such as (i) the large flexibility in optimizing the reaction conditions, e.g. the possibility of selecting solvents which are not compatible with the CE system, or (ii) no limitation to the reaction kinetics, provided a single derivative is formed with the analyte, (iii) the conditions during complexation do not have to be compatible with the electrophoretic buffer, and (iv) the availability of a wide variety of complexing agents. However, in this case, control of separation selectivity and maintenance of good peak shapes is an intriguing task. Use of the total complexation mode with ligands such as ethylenediaminetetraacetic acid (EDTA) or cyclohexane-1,2-diaminetetraacetic acid (CDTA) has made possible the separation of some higher-valent metal ions which cannot be separated in other systems. However, the generally low sensitivity of direct photometric detection remains a weak point of this approach. Therefore, new metallochromic ligands with high absorbing characteristics, which react with as many metal ions as possible and form a single complex only with each metal, should be applied.

3.1 Partial Complexation

When a complex-forming equilibrium is established by introducing a weak complexing reagent into the electrolyte, partial complexation is set up. As a result, several different complexes of metal ions may exist simultaneously due to stepwise complexation. For an analyte species present in several forms which are in equilibrium with rapid kinetics of interchange between the forms, the effective mobility of the analyte is defined as the weighted average of the mobilities of each of the forms[58,59] (Equation 2):

$$\mu_{eff} = \sum \mu_i \alpha_i = \frac{\sum \mu_i [ML_i]}{\sum [ML_i]} = \frac{\sum \mu_i \beta_i [L]^i}{\sum \beta_i [L]^i} \quad (2)$$

where μ_i is mobility and α_i is the distribution coefficient of the form i, $[ML_i]$ is the concentration of the complex ML_i, [L] is the concentration of the form of ligand forming the complex and β_i is the overall stability constant ($ML_0 = M$, $\beta_0 = 1$). Therefore, based on the nature of the complexing reagent and the concentration of free ligand, usually dependent on the pH of the electrolyte, effective mobility of complexed metal ions can be controlled.

Affecting the degree of complexation and resulting migration velocity is the concentration of the complex-forming reagent, [L]. The concentration effects on the electrophoretic mobilities of metal ions have been studied in several studies.[60–65] The majority of organic acids used as partial complexing reagents are weak acids and hence undergo acid–base dissociation equilibria in the electrolyte buffer. In the case of a monoprotic acid, Equations (3) and (4) apply:

$$HL \rightleftharpoons H^+ + L^- \quad (3)$$

$$K_a = \frac{[H^+][L^-]}{[HL]} \quad (4)$$

in which K_a is the acid dissociation constant of HL. Consequently, it is not the total concentration of a given reagent added to the electrolyte but the concentration of free ligand which determines the ability to differentially reduce the mobilities of metal ions. Also the pH of the electrolyte is another important factor since the concentration of free ligand is dependent on it.

A variety of carboxylic and hydroxycarboxylic acids are found to be suitable as partial complexing reagents for the separation of metal cations. Of various complexing reagents tested, α-hydroxy-isobutyric acid (HIBA) has been most popularly used.[66–71] Remarkable separation results for alkali, alkaline earth, transition and rare earth metal ions are shown in Figure 2. Lactic acid also appears to be advantageous in terms of separation selectivity,[72,73] and citric,[74] malonic,[75] glycilic,[76] tartaric[77] and oxalic acids[78] have been used to give good selectivity. A comparative study of 10 carboxylic acids as complexing agents showed that oxalate and citrate exhibited the largest selectivity changes, and the optimum pH for separating metal ions in the presence of the complexing carboxylic acid was close to the pK_{a1} of the acid.[79] A noticeable improvement of the separation can be obtained by the combination of two ligands which possess different abilities for the complexation, for example, HIBA and acetate,[80] or lactate and HIBA.[81] Using a lactic acid and 18-crown-6 buffer with imidazole for indirect UV detection, alkali, alkaline earth, and transition metal cations have been simultaneously separated by CE.[82]

Figure 2 Simultaneous separation of alkali metals, alkaline earths, and lanthanides. Carrier electrolyte: 10 mM Waters UVCat-1, 4.0 mM HIBA, pH 4.4, fused silica capillary 36.5 × 75 µm, 30 kV, hydrostatic sampling: 20 s per 10 cm, indirect UV detection at 214 nm. Peak identities: 1: Rubidium 2 ppm; 2: Potassium 5 ppm; 3: Calcium 2 ppm; 4: Sodium 1 ppm; 5: Magnesium 1 ppm; 6: Lithium 1 ppm; 7: Lanthanum 5 ppm; 8: Cerium 5 ppm; 9: Praseodymium 5 ppm; 10: Neodymium 5 ppm; 11: Samarium 5 ppm; 12: Europium 5 ppm; 13: Gadolinium 5 ppm; 14: Terbium 5 ppm; 15: Dysprosium 5 ppm; 16: Holmium 5 ppm; 17: Erbium 5 ppm; 18: Thulium 5 ppm; 19: Ytterbium 5 ppm. 3.2 Formation of Inclusion Complexes

Enhanced selectivity for the separation of alkali and alkaline earth cations can be obtained from a somewhat different partial complexation: inclusion complexation. The formation of inclusion complexes is observed in molecules having a well-defined cavity in their structure such as the crown ether. The dimension of the cavity in crown ethers makes those compounds ideally suitable for selective interactions with alkali and alkaline earth cations. According to this complexation principle, macrocyclic ligands magnify differences in mobility of only certain cations like K^+, Ba^{2+}, Sr^{2+} which interact specifically with 18-crown-6. As the charge of a metal ion remains unchanged during the complexation, the retardation effect on the migration velocity is owing to the charge density alterations for much bulkier crown-complexed cations. Apart from the resolution of ammonium/potassium and calcium/strontium pairs, other changes in selectivity, most dramatically the large change in migration time of barium, are noted.

Since the crown ether ligands are electro-neutral, free ligand concentration and thereby complexation is virtually unaffected by the pH and the only electrolyte variable to improve the selectivity is the total concentration of crown ether. In general, higher electrolyte concentrations of crown ether are favorable as they widen the range of effective mobilities of the cations.

Macrocyclic polyethers, mostly 18-crown-6, are commonly used in combination with a weak complexing acid in order to separate potassium/ammonium or sodium/lead(II) in the presence of other group cations. An impressive example of separation selectivity gained by the addition of 18-crown-6 to the lactate system is the complete resolution of Mg, Ca, Sr and Ba against a 1000-fold excess of sodium.[83] Clearly seen from the electropherograms, enhanced cation selectivity can be

achieved, for example, by an addition of a suitable crown ether to carrier electrolytes.

3.3 Complete Complexation

Separation of metal ions in the pre-capillary-complexed form presents a viable supplementary approach of improving selectivity. Pre-capillary complexation usually leads to the formation of complete complexes with the metal ions. Since most of the metal ion is in the completely complexed state under all electrolyte conditions, manipulating selectivity is not as easy as a partial complexation. However, depending on their charge and size, the strong metal complexes can migrate towards different electrodes, so several migration modes can be applied and more flexibility with regard to the choice of separation conditions can be obtained. When complexes of metal ions with a chromogenic reagent are used, very sensitive detection can be obtained by a direct detection method. Other benefits of fully complexed metal ions are the possibility of largely reduced interferences from complex sample matrices, the feasibility of analyzing metal species incompatible with carrier electrolyte or those that possess a slow rate of complexation, and good tolerance of sample pretreatment conditions.[84]

In general, the complexing reagent for complete complexation is required to be non-selective and to form a highly stable metal complex not to be dissociated in the CE system. Another requirement for complexing reagents in CE, unless the micellar-mediated CE systems are concerned, is the formation of charged complexes. To satisfy this requirement the ligand must contain at least one ionizable group, such as sulfonate, carboxylic or a quaternary ammonium group, which does not participate in complexation. A variety of complexing reagents has been previously reported. Among the most commonly used reagents, polyaminocarboxylic acids such as EDTA, CDTA and analogs appear to be most advantageous for the separation of different metal groups. These reagents are generally considered to form only 1:1 metal complexes with various metals. Even though a polydentate ligand forms very stable complexes, it can be used in the partial complexation mode if a competing ligand is added to the electrolyte to decrease the conditional stability constant of the primary ligand.[85]

A number of divalent metals and Fe(III) as complexes with EDTA have been separated.[86] A linear relationship between the electrophoretic mobility and the reciprocal of the square root of molecular mass of alkaline earth metal complexes has been obtained while other metals have some deviations. This was explained by differences in the degree of hydration of the complexes. CDTA has also been used for the separation of 32 divalent and higher valent metal ions.[87] Among them 23 metal ions have been separated in the baseline within 10 min. Numerous high valent metal ions such as Fe(III), Sn(IV), or U(VI) have been separated. The selectivity of the separation of lanthanide complexes was studied with EDTA, CDTA and two other polyaminocarboxylic acids.[88] The electrophoretic mobility of the complexed lanthanides was observed to be strongly dependent on the pH of the electrolyte. This was explained by the formation of mixed hydroxo complexes. Monodentate inorganic ligands such as cyanide or chloride are also regarded as good complexing reagents for the separation of precious metals, even though complexation conditions are difficult to control.[89] Most metal complexes in this category are negatively charged. Therefore control of EOF is required for coelectroosmotic mode. More applications of complete complexation have been presented in other reviews.[8,9]

4 MANIPULATING SENSITIVITY

A number of steps have been taken to overcome the limitations imposed by the lack of detection sensitivity of CE. Development of new sensitive detection systems is one of the most active research areas in CE in recent years. Alternative capillary geometries and improved optical design for the photometric detector is another approach toward sensitivity enhancement.[3] Using commercial systems, different on-column preconcentration approaches were developed, including sample stacking,[90] SPE,[91] on-line ITP,[92] and transient ITP.[93] Among them, sample stacking is one of the most promising techniques from the practical and economical point of view. In this section, some techniques used only in environmental analysis will be introduced. Reviews of methods manipulating sensitivity have been presented in other papers.[3,22]

4.1 Use of Detection Cells with Extended Optical Pathlength

In commercial CE with photometric detectors, the optical pathlength for detection is limited by the narrow diameter of the capillary column due to on-column detection. To extend the optical pathlength, various special detection cells have been designed, such as Z-cells, rectangular cells, multireflection cells, along the column end cells, bubble cells, etc.[3] Although these cells have enhanced sensitivity, they have also posed difficulty in manufacture and manipulation. They can even decrease separation efficiency. The bubble cell has been used in environmental analysis with an enhanced sensitivity of more than three-fold without degradation of resolution of closely migration peaks[94,95] and is now commercially available.

4.2 On-column Preconcentration by Sample Stacking

Sample stacking occurs as an on-capillary concentration technique. Commonly, when the injected sample has a lower ionic strength than the running buffer, sample stacking occurs. It can also occur during the electrokinetic injection process, or separation process in case of hydrodynamic injection. Since the conductivity in the sample is lower than that of BGE, the applied voltage is not distributed uniformly along the capillary between the two ends. The field strength is higher in the sample zone, which results in higher migration velocity of an analyte ion, whereas the field strength is lower in the electrolyte, which results in lower migration velocity of the analyte ion. The analyte ion will then stack up at the stationary boundary between the two zones, thereby increasing its concentration. Sample stacking in CE was reviewed by Chien and Burgi[90] and Song et al.[91]

In the simplest form of sample stacking, a plug of water or low concentration buffer containing the analyte(s) is injected onto the column filled with a relatively high ionic strength run buffer. On application of a voltage of 20–30 kV across the capillary, a high electric field is developed across the sample plug which drives its ionic species towards the higher ionic strength run buffer regions. Positive species such as metal chelates and metal ions will stack at the front of the sample plug in the direction of the CZE cathode. This leads to a decrease in the LOD of order of a factor of three[96] by the time the species has migrated to the detector. This stacking is limited to the size of the sample plug that can be injected.

A large plug of the sample can be injected. However, in this case, if the sample zone is too long, laminar flow, which originates from the different local EOF caused by the nonuniform distribution of the applied voltage, will occur and de-stack the stacked analyte ion. Therefore, the relatively large sample matrix zone during or after the stacking stage has been removed by taking advantage of EOF, which is called large volume sample stacking.[90,91] For anionic analytes, this involves field polarity reversion after the capillary is filled with sample. Then the sample matrix is pushed out of the capillary from the injection end by EOF, and anionic analytes move with a very high velocity towards the boundary between the sample and the buffer. The field polarity is switched back when the boundary is approaching the injection end of the capillary, which is indicated by the current approaching 95% of its highest value, i.e. the current when the capillary is solely filled with buffer. The LOD can then be improved by a factor of 200. The preconcentration of cationic analytes is similar, but demands a reversed EOF. However, in this approach, close monitoring of the variation on current is required for the just in time polarity switching for complete removal of the sample plug and the avoidance of sample loss. This can be solved by adding an EOF modifier, such as CTAB,[96] diethylenetriamine (DETA)[92] or ethanolamine[93] in the BGE to suppress the EOF, therefore the electrophoretic mobility of anions becomes higher than that of EOF.

Sample stacking can also be performed by electrokinetic injection with LOD improved by a factor of 1000; however, the reproducibility is very poor.

The reproducibility of large volume sample stacking with matrix removal as an on-column preconcentration technique was compared with that of normal injection,[97] giving a result of typically 4.0 vs 1.2% for peak area and no differences for migration time. It was indicated that this preconcentration technique requires samples having a relatively low and reproducible conductivity.

In normal sample stacking with hydrodynamic injection, the ionic strength of samples has a significant effect on sensitivity.[98,99] Higher ionic strength of a sample led to lower LOD. Recently, large volume sample stacking with matrix removal has been applied to the analysis of small organic and inorganic anions without polarity switching.[100] The pH is adjusted to the acidic range so that the EOF can be adjusted to be slower than the electrophoretic mobilities of small anions and more than 300-fold enrichment was readily achieved. In the analysis of methylmercury, the achieved LOD was 12 ppb with large volume sample stacking with matrix removal.[101]

Sample stacking can also be used in MEKC. For ionic analytes, the procedure is the same as in CZE. However, for neutral analytes the procedure has to be modified a little. Liu et al.[102] reported the accomplishment of sample stacking of neutral analytes by dissolving them in a micellar solution with a low concentration just above critical micelle concentration (CMC). The micelles were stacked up under applied voltage, and caused stacking of neutral analytes. Normal and reversed field polarity was used and produced a 75–85-fold increase in sensitivity for 1,2,4,7- and 1,2,4,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Susse and Muller[103] used sample stacking with reversed field polarity as an on-column preconcentration technique for the analysis of pesticides by MEKC. LODs between 0.01 and 0.1 ppb were achieved, where 30-fold preconcentration was attributed to sample stacking and 250-fold to SPE.

4.3 On-line Preconcentration by Isotachophoresis

ITP can be used as a preconcentration technique for diluted samples in CE. In this procedure a small quantity of the sample is introduced at the interface of a discontinuous buffer system, consisting of a leading and a terminating electrolyte. The analyte ions migrate between a leading ion having the highest mobility and a terminating ion having the lowest mobility in the

buffer system. Under applied voltage, the analyte ions stack up and migrate as consecutive zones, according to their mobility between the leading and terminating ions. Establishing ITP conditions at the beginning of a run provides a method for on-column preconcentration; separation then proceeds by zone electrophoresis. From the point of view of trace analysis, ITP can be considered a good preconcentration technique for CE but coupling ITP and CE instrumentation can be rather complex. Recently, ITP coupled with CZE has been shown to be capable of being performed in a single capillary by taking advantage of a counterflow. Moreover, ITP can also be performed before CZE separation as a transient preconcentration step (TITP) in commercial CE instruments by carefully selecting the CZE electrolyte as a leading or terminating electrolyte to form an ITP buffer system with an additional electrolyte. There is a review on these two techniques.[104]

4.4 Preconcentration by Solid Phase Extraction

SPE inside the capillary is another preconcentration technique capable of providing a concentration factor of $10–10^6$, effective especially for aqueous samples. This solid phase can be incorporated as a short plug at the beginning of the capillary, or as a hydrophobic stationary phase bonded to the inner wall such as an on-line coupled C_{18}-coated column.[105] However, in the latter case, because of the low amount of the wall-coated stationary phase, the enrichment factors were limited to 10–35-fold. When in-column SPE is applied, the sample must be cleaned before it is introduced into the capillary and cannot be introduced directly because of the risk of blocking the system.

4.5 Use of Alternative Detection Techniques

To improve the detection sensitivity of CE, a range of other detectors has been developed. Among them, indirect LIF, CL, ED and ICPMS received much attention as popular choices for high-sensitivity detection for inorganic ions. The advantages, disadvantages and limitations of each technique are presented in section 2.3.

5 APPLICATIONS

This section will give a general overview of CE procedures suitable for practical application. Therefore, some selected results of both basic and applied research will be presented. The following is divided into sections dealing with metal cations, metal speciation, inorganic anions and simultaneous determinations of cations and anions.

5.1 Determination of Metal Cations

The main strategy for the simultaneous determination of metal cations by CE is complexation. Many metal cations have nearly identical charges and identical hydrated ionic radii. Therefore, all complexations, whether weak, strong or inclusive, need to be applied for proper separations.

The most significant agent is HIBA, widely used for the separation of alkali, alkaline earth metals, transition metals, and lanthanide. Using the on-capillary complexation principle, separation of 19 cations in only a few minutes[3] has been accomplished as shown in Figure 2. A quinine sulfate buffer system with HIBA has been used for the indirect fluorescence detection of several alkali and alkaline earth metals.[106] Reagents such as HQS[107] and 1,10-phenanthroline[108] have been employed for the quantification of zinc(II) and iron(III), respectively, in tap water samples without preconcentration. The latter can lead to a loss of analyte and peak broadening. There have been several examples indicating that this complexation technique makes it possible to reduce interference from complex sample matrices (electroplating solutions,[109,110] ores,[111] catalysts,[107] ceramics,[107] etc.).

Complete complexation with pre-capillary mode has been applied for the separation of a number of alkali and alkaline earth metal ions.[112] EDTA was used as complexing reagent and pyridine as UV chromophore for indirect UV detection. CDTA also was used for the separation of lanthanides as anionic complex.[113] For the determination of precious metals, complexation with chlorine or cyanide is a popular method, even though more rigid control of complexation conditions is required. Os(IV), Pt(IV), Ir(III), Pd(II), Au(III), and Rh(III) were separated efficiently within 5–6 min as chloro complexes with detection limits of 0.1–0.6 ppm.[114]

Enhanced selectivity for alkali and alkaline earth metals can also be obtained with a suitable macrocyclic polyether (like crown ethers)[11] or polyethylene glycol[12] incorporated into the electrolyte. As an additional separation mechanism with complexation function, stronger complexing reagents, e.g. EDTA, but under conditions of incomplete complexation,[13] are of certain use to manipulate differences in effective mobilities of alkaline earths and magnesium as well. The more interested reader should refer to the reviews listing the experimental conditions of determination of metal ions by CE from almost all publications before 1997.[8,9]

5.2 Metal Speciation

The ability to resolve different oxidation states of a metal is a distinct benefit of CE. Since it causes a minor disturbance on the existing equilibrium between different species, CE gives a unique promise for speciation purposes. Most of the studies performed on speciation

have been focused on the optimization of separation parameters in order to separate various metal species in environmental, biological, and industrial samples. Since a recent review has been published,[7] some recent examples of the application of CE to the metal speciation will be presented in this section.

Complexation is the most valuable approach for performing metal speciation on different oxidation states. Separations of metal ions in a free, uncomplexed form are comparatively rare in the practice of CE for metal speciation. Complete conversion of metals into charged complexes, which takes place upon the addition of a complex reagent to a sample before introducing to a capillary, yields differences in charge densities while the initial concentration ratio of different oxidation states is preserved. For speciation involving metal oxidation forms of opposite charges, pre-capillary complexation is a straightforward strategy to impart the same charge and electrophoretic direction on the species.[115,116]

Among the numerous metal cations that exhibit toxic effects on humans and plants or aquatic organisms, the most frequently studied ones are aluminum, iron, copper, manganese, nickel, and zinc. Inorganic Al(III) and its complex forms appear to be much more toxic than organically bound aluminum. To study the distribution of aluminum and its inorganic and organic complexes in aqueous solutions by CE, indirect UV detection was performed with imidazole as a UV-absorbing component of the electrolyte.[117] Good resolution was obtained for the analysis of a sample solution containing four aluminum species: Al^{3+}, AlF^{2+}, AlF_2^+, and Al (oxalate)$^+$ during a period of less than 5 min. As a certain disadvantage for practical purposes, high detection limits (10 μM) shall be noted; these are of 1–2 orders of magnitude above those needed for use in natural waters.

With CE separation of Fe(II) and Fe(III) ions the major problem is the selection of complexing agents suitable for the derivatization of both iron species. There are some reports which show the possibility of separating the Fe(II) and Fe(III) ions by CE after pre-capillary complexation with EDTA and CDTA.[118]

The utility of micellar-mediated CE to differentiate Fe(II) and Fe(III) following derivatization with 4-(2-pyridylazo)resorcinol (PAR) was reported[119] (Figure 3). The limits of detection accomplished in the visible spectral region (500 nm) were in the submicromolar range. Later, in an attempt to enhance the sensitivity, on-column complexation with PAR, in combination with sample stacking as an enrichment step, provided a 100-fold improvement in the detection limit for iron(II) over the precolumn complexation method.[120] This allowed the authors to apply the procedure to the development of the analysis of a pond water sample. Iron species, while they are stable in the carrier electrolyte solution,

Figure 3 Electropherogram of Fe(II)-PAR and Fe(III)-PAR complexes. 75 μm × 50 cm capillary, 10 mM phosphate buffer (pH 8), 75 mM SDS and 1×10^{-4} M PAR. Peaks: S: acetone; 1: Cr(III); 2: Co(II); 3: Cu(II); 4: Pb(II); 5: Fe(II); 6: Zn(II); 7: Fe(III); 8: Cd(II). (Reprinted from A.R. Timerbaev, O.P. Semenova, P. Jandik, G.K. Bonn, 'Metal Ion Capillary Electrophoresis with Direct Ultraviolet Detection Effect of a Charged Surfactant on the Migration Behavior of Metal Chelates', *J. Chromatogr. A*, **671**, 419–427 © 1994, with permission from Elsevier Science.)

can be determined without derivatization by means of an element-specific detector such as inductively coupled plasma atomic emission spectroscopy (ICPAES) or ICPMS, as was demonstrated by Olesik et al.[171] Since the analytes exist in a highly mobile cationic form in this case, an analysis time of 1 min or less is attainable. Furthermore, separation of different metal ions from each other was not needed due to the high selectivity of ICP spectrometry.

There is a continuing interest in the determination of chromate ion, the most toxic of chromium species, motivated by the fact that chromium is commonly used in various industries and a considerable amount may be released into the environment. The first successful speciation of both oxidation states of chromium through CE separation was achieved by converting Cr(III) into a negatively charged complex with CDTA in order to impart the same charge and similar mobility to chromium species.[115] The separated anionic species were monitored by direct UV measurements at 214 nm. The procedure was applied to rinse water and processing solution samples and was found to be free of interference from transition metal impurities. Similar results have been obtained with EDTA instead of CDTA for the separation of the Cr(III) and Cr(VI) species by Jung et al.[116] with the same separation strategy.

Speciation of arsenic is of particular interest because of the wide range of toxicity exhibited by the different chemical forms. CE has been widely used for the separation of arsenic compounds.[121–123] Direct UV absorption detection at a wavelength between 190 and 200 nm is the most commonly employed. However, the arsenic concentrations to be detected are generally at ppm levels in aqueous solutions. Therefore on-column preconcentration such as field amplified injection[8] has been applied or coupling of CE with ICPMS has been actively developed.[124–128]

Selenium can be a toxic or an essential element depending on its chemical state. Several studies have focused on applying CE for the separation of selenium species using various electrolyte composition and detectors.[124,126]

For the speciation of oxoanions of selenium, or arsenic, the coelectroosmotic migration mode by reversing the direction of EOF towards the anode is suitable for resolving oxoanions and organic anionic forms of selenium.[122,123,129] Counterelectroosmotic migration modes have also been applied for the speciation of oxoanions of arsenics, where variations of the electrolyte pH offer an effective means for separation efficiency control over metal oxoanions. As anions of polybasic acids, these species are pH-sensitive and show a strong dependence of ionic mobility on the carrier electrolyte acidity. The anionic analytes can be transported towards the cathode by the EOF, if their charge is reduced by using slightly acidic or neutral buffers. This combination of cathodic EOF and detection is favorable for the separation of arsenic compounds.[122,130] If the electrophoretic mobilities of oxoanions are greater than that of EOF, they can migrate counterelectroosmotically towards the anode.[131] This is the case for arsenates and selanates which exist as doubly-charged anions over a wide pH range. For their fast separation from the slowly migrating arsenite and selenite species, the pH of the electrolytes should be higher than 10 where all anions are essentially ionized. To shorten the separation time further, an EOF modifier like a cationic surfactant can be incorporated into the electrophoretic buffer in order to suppress or reverse EOF.[132]

In practice, however, applications of the procedures developed to date are rather scanty, evoking problems with real sample matrices. Few exceptions deal with the analysis of waters and soil extracts,[133] coal fly ash,[134] water samples from a tailing of tin mine processing,[135] spiked water[109,130] and urine[110] samples.

The toxicity of many organometallics often exceeds that of the same metal inorganic species, which makes the speciation of paramount importance. Separation of cationic organomercurials and inorganic mercury(II), facilitated by the formation of their complexes with cysteine, was examined by Medina et al.[136] For methylmercury, which is recognized as one of the most dangerous chemical species in the environment, direct UV detection of the cysteine complex provided a detection limit as low as 10 pg. The CE procedure developed has proved to be efficient for rapid and simple determination of methylmercury (at the level of low ppb) in biological materials of marine origin. CH_3Hg^+ was extracted from the sample (as chloride derivative) with toluene, then back-extracted with a 0.1% cysteine solution and, finally, the aqueous extract was subjected to CE analysis. A unique possibility of MEKC to separate both neutral and charged analytes was exploited for simultaneous separation of organoselenium and organolead compounds.[137] The complete resolution of a test mixture of trialkyllead and phenylselenium compounds has been accomplished. The competitive interactions of the analytes with electrolyte components, sodium dodecyl sulfate and β-cyclodextrin, taking place via hydrophobic and host–guest complexation mechanism, respectively, appear to govern the migration pattern observed. For organotin species,[138] the migration behavior in MEKC was found to be dominated by the distribution ratios of the solutes between the aqueous electrophoretic and micellar phase, i.e. by their hydrophobicity.

Note that a majority of the reports involving water or biological matrices have only demonstrated the analysis of spiked samples, as for many metalloorganic contaminants the concentration levels in these objects are beyond the detection sensitivity of CE analysis. For example, Ng et al.[137] developed a scheme for the determination of trimethyl- and triethyllead, which includes preconcentration by means of liquid–liquid extraction and evaporation and then MEKC. However, the compounds under investigation were not even detected in a water sample collected at a heavily used car park, since they were present at levels below the detection limits. Neither allowed the enrichment by more advantageous membrane SPE on a C_{18} disk to determine organolead and organotin species in non-spiked water samples using MEKC.[138] A combination of subcritical fluid extraction, using chlorodifluoromethane as solvent, and MEKC has been applied for the determination of alkyllead and alkyltin compounds in solid samples.[139] To improve the recoveries of two less hydrophobic trimethyl species, sodium diethyldithiocarbamate was added as a complexing agent to the soil sample before extraction. However, direct analysis was only possible for a rather high content of dibutyltin stabilizer (1.2–1.5%) in poly(vinyl chloride) plastic.

5.3 Inorganic Anion Analysis

The determination of common inorganic anions such as fluoride, chloride, bromide, nitrite, nitrate, phosphate,

and sulfate, is a significant factor in the characterization of the quality and the extent of contamination of water. Since they do not have enough chromophoric characteristics and the direction of electrophoretic mobility of anions is opposite to that of EOF, in determining them by CE with untreated fused silica capillaries, the common procedure includes a reverse of EOF from cathode to anode and indirect detection. Many of studies performed have been focused on the optimization of separation parameters of electrolyte based on above two strategies.[140–150] Jandik and Jones systematically developed the separation procedure for anion analysis,[3,25] and accomplished spectacular separations of inorganic anions, as well as small organic anions in a very short time. CE has been applied to the anion analysis of a variety of environmental samples, such as natural water,[151] drinking water,[152] tap water, water from the space shuttle and space station,[153] wastewater,[154] seawater,[155] soil solution,[133,156] silicon product,[157,158] toothpaste,[159,160] single rain, fog, and cloud drops,[161] aerosols[161] etc. A specially developed sampling procedure has been applied in the analysis of a single rain, fog, or cloud drop. This shows that CE can be applied to the quantitative, multicomponent chemical analysis of ultrasmall volumes, like a single rain or fog drop. CE has been compared with IC in anion analysis.[153,158,162,163] It was reported that CE has been proved to be a good alternative to IC since it gives usually good agreement with IC in their results even though their detection limit is usually a little inferior to IC. A comparison for the results of CE and IC is shown in Figure 4.

Speciation of sulfur, nitrogen, or chlorine in various water samples has been performed.[164–166] Numerous chlorine-containing anions with different oxidation states, such as chloride, chlorite, chlorate, and perchlorate in tap water, swimming pool water, and bleaching preparation were separated by CE and IC.[166] CE has advantages for the quantitative determination of chlorine-containing anions in several hundreds ppb level in the presence of a large excess of chloride or nitrate and sulfate.

Figure 4 Comparison of first 3.1 min of an IC separation vs a CE separation. IC chromatogram (b) separates only 3 anions: fluoride, carbonate, and chloride using a Waters IC-Pak A, borate-glutamate eluent at 1.2 mL min^{-1} and Waters 431 conductivity detection. The electropherogram (a) separates 36 anions using a Waters Accusep fused silica capillary with indirect detection method. (Reprinted from W.R. Jones, P. Jandik, 'Controlled Changes of Selectivity in the Separation of Ions by Capillary Electrophoresis', *J. Chromatogr.*, **546**, 445–458 © 1991, with permission from Elsevier Science.)

5.4 Simultaneous Determination of Cations and Anions

A simultaneous determination of inorganic cations and anions in a single analysis is both advantageous and necessary. However, no specific technique is available for this purpose up to now. CE can be developed for simultaneous determination of cations and anions but it still remains a challenging problem. Cations and anions were usually separated using different BGEs under different conditions in CE. Following are some reports about the simultaneous determination of cations and anions. A common strategy among them is taking dual electrolyte for indirect detection of cation and anion and finding the optimum EOF.

A simultaneous determination of small cations and anions has been performed in one single electrophoretic run using one capillary and one detector.[167] In this

Figure 5 Separation of 22 anions and cations. Electrolyte: 6 mM 4-aminopyridine, 2 mM H_2CrO_4, 30 μM CTAB, pH 8. Injection conditions: hydrodynamic injection; capillary ends elevated to a height of 10 cm for 40 s (cathode end) and to 5 cm for 20 s (anodic end). Time between the injections, 80 s. Detection principle: indirect UV at 262 nm, peak reversal. The linear baseline drift observed during the first 3 min was corrected for. Peak identification: 1: $S_2O_3^{2-}$; 2: Br; 3: Cl; 4: SO_4^{2-}; 5: NO_2; 6: NO_3^-; 7: WO_4^{2-}; 8: MoO_4^{2-}; 9: citrate; 10: maleate; 11: fumarate; 12: F^-; 13: HPO_4^{2-}; 14: Cs^+; 15: K^+; 16: NH_4^+; 17: HCO_3^-; 18: acetate; 19: Na^+; 20: Ca^{2+}; 21: Mg^{2+}; 22: Li^+. (Reprinted from P. Kuban, B. Karlberg, 'Simultaneous Determination of Small Cations and Anions by Capillary Electrophoresis', *Anal. Chem.*, **70**, 360–365 © 1998, with permission of the American Chemical Society.)

case the sample is injected into the one end of the capillary and subsequently into the other end of the capillary. Cations and anions migrate against each other toward the center of the capillary where the detection window is placed. 4-Aminopyridine and chromate with CTAB have been used as electrolytes. 22 small inorganic and organic anions and alkaline and alkaline earth metal cations were separated within 5 min as shown in Figure 5. Adapting the same sample injection strategy with different electrolyte composition, chloride, sulfate, hydrogen carbonate, potassium, ammonium, calcium, sodium and magnesium ions were simultaneously separated.[168] Two electrolyte systems based on imidazole-nitrate and copper(II)-ethylenediamine-nitrate have been applied for indirect UV detection at 214 nm.

Introducing an ion-exchange electrokinetic chromatography mechanism, simple simultaneous determination of inorganic anions and kinetically stable metal-PAR chelates has been obtained.[143] The addition of cationic polymers to the background electrolyte reverses EOF and decreases electrophoretic mobility of anions according to their abilities to associate with polymeric cations. Chromate was chosen as a background electrolyte anion because it enables indirect UV detection of transparent anions at 254 nm and does not affect the direct detection sensitivity of chelates at 490 nm. Rapid (4 min) separation of Co(II), Ni(II) and Fe(II)-PAR chelates and of 11 inorganic anions was obtained.

Benzylamine, imidazole, benzenesulfonic acid, sulfosalicylic acid, and pyromellitic acid were tested as the components of the BGE for simultaneous separation of cations and anions.[169] The electrolyte components and control of the migration velocity were found to be the main factors for the separation.

6 CONCLUSIONS AND FUTURE TRENDS

As discussed in the previous sections, CE is an analytical separation technique that has great potential for environmental analyses. This is reflected in the rapidly increasing number of publications on CE. A diversity of inorganic species in real samples has already been proved to be amenable to the analysis by CE, and more can be expected in the years ahead. CE procedures provide high separation efficiency and high-speed separation, and are simple enough to be used on a routine basis. In application, however, limitations imposed by the lack of detection sensitivity complicate the technique's use and impede its wide acceptance. To overcome sensitivity problems in the determination of metal ions, the coupling of CE with ICPMS is now being attempted. This is done as an alternative to the two research techniques competing with each other. By doing this, not only the sensitive determination of elements but also particular speciation information of each element can be obtained. Interface design, however, is still being developed.

The advantages of CE compared to IC are speed, resolution, and the lack of a need for gradient elution. Operating costs are considerably lower, since ion-exchange columns are usually expensive. However, when a comparison on the data was made, the precision, linearity, and concentration LOD of CE were usually inferior to those of IC for the same analysis.[170] However, CE has the capability of analysis in three different areas:

1. analysis in complex matrices,
2. simultaneous determination of inorganic and organic pollutants and
3. metal speciation with simple pretreatment of sample and simple procedure.

As such, this technique remains as a complementary technique for IC or HPLC.

Another future of CE is in creating a miniaturized (or micro-) total analysis system. CE contains the qualities of speed, sensitivity, and small sample volumes that are desirable for a micro-total analysis system.[170] Using microlithography on glass structures, CE has been carried out on a chip. These chips allow for low sample volumes, fast analysis times and good separation efficiencies and has a possibility to be developed for a portable system that would be particularly useful in field analysis of environmental samples.

ABBREVIATIONS AND ACRONYMS

BGE	Background Electrolytes
CDTA	Cyclohexane-1,2-diaminetetraacetic Acid
CE	Capillary Electrophoresis
CEC	Capillary Electrochromatography
CGE	Capillary Gel Electrophoresis
CIEF	Capillary Isoelectric Focusing
CITP	Capillary Isotachophoresis
CL	Chemiluminescence
CMC	Critical Micelle Concentration
CTAB	Cetyltrimethylammonium Bromide
CZE	Capillary Zone Electrophoresis
DAD	Diode Array Detector
DETA	Diethylenetriamine
ED	Electrochemical Detection
EDTA	Ethylenediaminetetraacetic Acid
EOF	Electroosmotic Flow
HIBA	α-Hydroxy-isobutyric Acid
HMH	Hexamethonium Hydroxide

HPLC	High-performance Liquid Chromatography
HQS	8-Hydroxyquinoline-5-sulfonic Acid
IC	Ion Chromatography
ICPAES	Inductively Coupled Plasma Atomic Emission Spectroscopy
ICPMS	Inductively Coupled Plasma Mass Spectrometry
ITP	Isotachophoresis
LIF	Laser-induced Fluorescence
LOD	Limit of Detection
MEKC	Micellar Electrokinetic Capillary Chromatography
PAR	4-(2-pyridylazo)resorcinol
SPE	Solid Phase Extraction
TCDD	Tetrachlorodibenzo-*p*-dioxin
TITP	Transient Preconcentration Step
TTAB	Tetradecyltrimethylammonium Bromide
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible

After the industrial revolution considerable emphasis was placed on monitoring organic, inorganic and organometallic substances in the environment. Environmental contaminants include products of combustion, vapors, gases, industrial solvents, dusts, agricultural fertilizers, pesticides, radioisotopes, noise, ultraviolet light and certain microwave electromagnetic radiations.

Contaminants that are present in strong enough concentrations to pose an immediate threat to life or to cause unmistakable cases of disease or acute poisoning are usually readily apparent, and experience has led to the development of adequate, but by no means perfect, environmental control measures. The effects of environmental contaminants are related to time as well as concentration or intensity. Time factors become increasingly important when low concentrations of contaminants do not produce ill effects until after months or years of exposure. Trace analytical methods, therefore, play a very important role in environmental analyses. They are required for the detection and identification of chemical pollutants present in the environment. It is essential that the analytical methods applied are suitable and that they yield reliable data. These methods have to have high sensitivity, as many toxic chemicals are present in environmental samples at microgram per liter levels. Furthermore they have to cover a large dynamic range, and most important they have to be inexpensive. Voltammetry fulfills all of these features and it can be used both in trace metal analyses and in the determination of organic compounds in environmental samples. This article will cover the determination of inorganic pollutants in air, water and soil, using electrochemical (EC) methods.

1 INTRODUCTION

In recent years considerable emphasis has been placed on monitoring chemical pollutants in the environment. Most people are exposed to a large number of chemicals emitted from different sources. This increased exposure is viewed, by some, as an inevitable side effect of technological advancement. For example, the inhabitants of cities are exposed to large concentrations of lead caused by the combustion of leaded petrol in cars. Although many countries have taken measures to prevent the accumulation of lead in the atmosphere, soils, waters, and so on, by abolishing or restricting the use of tetraethyllead as a gasoline additive, developing countries still suffer from a steady increase in lead levels. Even at relatively low concentrations, lead acts as a metabolic poison and accumulates in bones by replacing calcium. It inhibits the enzymes needed for the synthesis of hemoglobin owing to its strong interaction with SH groups. One of the toxic manifestations associated with an increase of lead level in the body in young children is a reduction in their learning ability. Despite this knowledge, it is only in the recent past that there has been any attempt to reduce the concentration of lead in petrol.

The contamination of the environment is widespread. Nriagu and Pacyna[1] have presented a worldwide inventory of industrial and municipal discharge of metals into soils and the aquatic ecosystem. The annual discharge exceeds the combined output of all radioactive and organic wastes generated each year as measured by the amount of water needed to dilute such wastes to drinking water standards. One of the important features that distinguishes metals from other pollutants is that they are not biodegradable. Once they have entered the environment, their potential toxicity is controlled to a large extent by their chemical form.

Toxic metals, such as Cd, Cu, Ni, Pb, Zn, and so on, and acid rain contribute substantially to the pollution of land and waters and cause increasing damage to the various components of both, especially forests. Determination of these ions in wood samples using inverse differential pulse (DP) voltammetry showed that Pb and Cd concentrations were higher in wood from polluted regions than in nonpolluted regions. The difference between natural changes and the effects of industrial development during the last 100 years is the amount and speed of alteration, which deprives the biological systems of any chance of adapting, albeit slowly, to the newly created conditions. Today the average adult human body contains about 10 times the amount of lead found in mummified Egyptian bodies.

Increasing environmental pollution by toxic metals and also by organometallic and organic pollutants calls for reliable analytical procedures for their control in air, water and in soil. There has been an increasing public awareness of the dangers of exposure to toxic substances. Obviously there is a need to control and manage the environmental burden caused by ''chemical pollutants''. Hence research to ascertain the levels and pathways of these environmental pollutants has become more important. Trace analytical methods play a very important role in environmental analysis. They are required for the detection and identification of ''chemical pollutants'' present in the environment. Trace analytical determinations, subsequent to sampling and sample preparation steps, are usually carried out using instrumental methods. However, in order to be suitable for trace analysis, these methods must fulfill certain basic requirements. They need to have high sensitivity, as many toxic chemicals are present in environmental samples at microgram per liter levels. Furthermore, the dynamic range should be large, covering a concentration range typically from several hundred microgram per liter down to microgram or even picogram per liter levels. In situations where environmental levels of hazardous chemicals are to be established, an extension of the detection limit down to nanogram concentrations is essential. A further requirement of any instrumental method is that it has the necessary selectivity to deal with the problem in hand. The most important consideration in trace analysis is accuracy; that is, the closeness of agreement between the observed result and the known or true value. There now exist a large number of instrumental methods, but not all incorporate the aforementioned requirements. Among the most suitable are the EC methods of polarography and voltammetry. Voltammetry in particular has proved its usefulness both in the fields of trace metal analysis and in the determination of organic compounds in environmental samples.

2 ELECTROCHEMICAL METHODS

For environmental analysis, like every other kind of analysis, the need is for simple, reliable and viable techniques. Analyses are costly, and running costs particularly can be very high. The task of the analytical chemist is to choose the most appropriate procedure in order that the desired information about the particular material of interest can be provided. Next to advanced electroanalytical techniques, modern atomic absorption spectrometry (AAS), inductively coupled plasma atomic emission spectrometric and inductively coupled plasma mass spectrometric methods are commonly used in industrial, technical and control laboratories. Neutron activation analysis (NAA) is a powerful detection method but costly both in terms of investment and operation expenditure. The features that make electroanalytical methods competitive techniques are the very large useful concentration range ($1-10^{-10}$ M), the larger linear ranges available in many commonly used instrumental techniques, the ability to assay dissolved and solid samples, the ability to speciate on the basis of complex liability and to distinguish between different states of valency, and the immunity of the matrix to samples with high ionic content, and so on. Perhaps the most important point with respect to environmental analysis is that polarography and voltammetry are among the very few techniques that are equally suitable for analysis of inorganic, organometallic and organic compounds to concentrations below $10^{-9}-10^{-10}$ M, and surfactants using tensammetric techniques. Inductively coupled plasma mass spectrometry (ICPMS), for example, has a limited capability for the determination of organic pollutants. Modern electroanalytical methods are applicable to all toxic metals and metalloids of environmental and toxicological relevance. Metals of particular importance in freshwaters that can be easily determined by EC techniques are Cd, Cr, Cu, Hg, Ni, Pb and Zn.

Polarography and voltammetry rank today as low-cost techniques. The instrumental costs, degree of automation and the time required per determination are related in a complex way to the economics of the laboratory. Costs and expertise virtually exclude installation of an ICPMS system in a smaller routine laboratory. If the prices for purchase are compared (ICPMS costs 400 000–600 000 DM, AAS costs 25 000–150 000 DM, polarography and voltammetry cost 10 000–50 000 DM), it is clear that voltammetric instruments are much cheaper. The operating costs are very high for ICPMS due to the large amounts of Ar ($13-18\,L\,min^{-1}$) consumed; the costs are medium for AAS but again very low for voltammetric analyses.

Polarography and voltammetry are well-known EC methods which can be used to study solution composition through current–potential relationship. Polarography is

the branch of voltammetry that is used to investigate solution composition by the reduction or oxidation of ions or molecules at a dropping mercury electrode (DME) under the influence of an applied potential.[2] Direct current (DC) polarography involves measurement of the current variation at a DME as the applied potential ramp is linearly changed with time. As a result of the charging current at the DME a significant background current is observed, which limits the sensitivity of DC polarography to concentrations in the 100 $\mu g\,L^{-1}$ region.

An increase in the ratio of faradaic current to charging current has been accomplished by pulse polarography.[3] One of the most widely used pulse modes in trace analysis is DP polarography. In this mode, small potential pulses are superimposed over a conventional DC voltage ramp and applied to the DME near the end of the drop lifetime. The current is sampled just before application of the pulse and again at the pulse when the charging current has decayed. It is the difference between these two current measurements that is displayed. Hence the ability of DP polarography to discriminate against the charging current lowers its limit of detection over DC polarography. Because DP polarography is an extremely sensitive method, it is applicable to both inorganic and organic analysis, yielding peaks for concentrations in the microgram per liter to milligram per liter range.

There are at least three types of catalytic current which should not be intermixed:[4]

1. Catalytic reduction of hydrogen ions caused by a decrease in overpotential, resulting usually from interaction of hydrogen ions or other proton donors with the oxidized or reduced form of a catalyst adsorbed at the electrode surface. Numerous organic compounds containing sulfur or nitrogen (both acyclic and heterocyclic) are examples of such catalysts.
2. Catalysis of hydrogen evolution by platinum group metals, either in the solution or at the electrode surface.
3. Catalytic currents caused by a homogeneous chemical reaction, e.g. to a reoxidation of a metal ion, reduced electrochemically to a lower oxidation state. Such catalytic currents increase with increased concentration of the oxidizing agent and were observed in particular in the presence of Fe(III)/Fe(II) and Ti(IV)/Ti(III) couples as well as some complexes of Mo(VI) and Mo(V).

To increase the sensitivity above that offered by pulse and square-wave techniques, an accumulation of the species to be determined at the electrode surface is carried out. For this purpose voltammetric methods such as anodic stripping voltammetry (ASV), cathodic stripping voltammetry (CSV) or adsorptive stripping voltammetry (ADSV) employ stationary mercury electrodes or solid electrodes such as glassy carbon or gold. These methods are among the most sensitive voltammetric methods used in environmental analysis. Stripping voltammetry involves two steps.[5] In the first step, the analytical species of interest are deposited either as amalgams, as mercury salts or as adsorbates onto a stationary electrode such as a hanging mercury drop electrode (HMDE) or mercury film electrode (MFE). The time required for the deposition step depends on the concentration of the analyte present. It is important that the conditions used in the deposition step, such as deposition potential, deposition time and stirring rate, are strictly controlled to ensure reproducible results. The second step involves stripping the deposited species from the electrode back into solution. The most commonly used waveforms in the stripping step are the linear sweep and DP modes. The DP waveform has become more popular because it is more effective in discriminating against charging currents and permits lower detection limits. The magnitude of the stripping current is proportional over a certain range of concentrations and deposition times to the concentration of the species of interest.

So far, stripping voltammetry has proved to be a very useful technique in the determination at the subnanomolar concentration level of some 25 metals that deposit electrolytically and form stable amalgams with mercury. However, some heavy metals, i.e. Ni, Co, and Ti, do not possess these properties and, consequently, cannot be determined by conventional stripping voltammetry. Their determination has then been accomplished by ADSV.[6] In this technique, the preconcentration step is carried out by adsorbing a metal chelate at the surface of the electrode. The reduction current of either the metal ion or the ligand in the adsorbed complex is used to quantitate the surface bound species and this current is directly related to the metal concentration in the bulk of the solution. Since most metal–chelate complexes have a hydrophobic nature and show a marked tendency to adsorb onto the mercury electrode, this preconcentration scheme does not necessarily require that a preconcentration potential be applied to the electrode. This fact enables the avoidance of many interferences caused by electroactive impurities present in the sample. On the other hand, the presence of surfactants should be avoided for they might compete for the adsorption sites of the electrode, thus decreasing the stripping signal. ADSV has been applied to the simultaneous determination of Ni and Co in a variety of real samples including plants, fruits, body fluids[7] and rainwater,[8,9] using dimethylglyoxime (DMG) as chelator. Samples are adjusted to pH 9.2 with ammonia buffer followed by addition of DMG. A potential of

-0.7 V is then applied to the working electrode while the solution is stirred for several minutes. Subsequently, the adsorbed $Ni(DMG)_2$ and $Co(DMG)_2$ are reduced by scanning the potential in the negative direction. ASV could also be applied for the determination of selenium(IV) by using the adsorptive properties of selenium–TGA (thioglycolic acid) complex in 4 M HCl.[10] Here, the deposition was carried out for 2 min at -0.1 V and the response was recorded by scanning the potential from -0.1 to -0.7 V. A reduction peak at -0.46 V was observed and 2×10^{-8} M Se(IV) could be determined. Linear scan voltammetry can be applied to analyte concentrations of 1 $\mu g\,L^{-1}$, whereas the DP mode is used for concentrations down to 1 $ng\,L^{-1}$. The sensitivity of ADSV is greatly enhanced by the fact that the stripping step proceeds from the adsorbed layer rather than from the whole of the electrode. For this reason the use of this technique has been extended to the analysis of metals that traditionally had been determined by ASV.

In stripping voltammetry, the sensitivity of the method depends very much on the type of working electrode used. An HMDE may be used for the analysis of trace metals down to several micrograms per liter, an MFE on the other hand may be employed for even lower concentrations.[11] When mercury electrodes are used in ASV, about 20 amalgam-forming metals may be determined.[12] By contrast, metal ions such as selenium, tellurium, arsenic, mercury and silver may be determined using solid electrodes such as the glassy carbon electrode (GCE) or gold.[12] A chemically modified GCE in conjunction with differential pulse anodic stripping voltammetry (DPASV) has been used to measure Cu at concentrations as low as 100 $ng\,L^{-1}$ in laboratory prepared solutions.[13] The properties of the dialysis membrane and the advantages of the MFE have been brought together in a rotating glassy carbon membrane covered MFE.[14] The use of this electrode enabled detection of 97 $ng\,L^{-1}$ of Cd in aqueous solutions when the DPASV mode was employed, the response being linear over three orders of magnitude.

Carbon paste chemically modified electrodes are very simple to prepare and have been used to determine Ni(II) in a variety of reference materials, including water, coals and sediments.[15] Here Ni(II) was chemically deposited on the modified electrode and the DP voltammetric determination was carried out after transferring the electrode to a separate buffer. After a 240-s preconcentration period, up to 0.050 μM Ni could be detected. A novel strategy for electrode modification has been the incorporation of a microorganism as a modifier in a carbon paste electrode.[16] The common brown alga shows a strong affinity towards copper and advantage was taken of this fact to bioaccumulate Cu(II). A further example is the development of a gold film microelectrode formed by plasma-sputtering gold onto carbon fibers.[17] This electrode has been used for the detection of mercury using DPASV, with a detection limit of 3.7 $\mu g\,L^{-1}$.

Catalytic polarography is used also for increasing the sensitivity of the measurement. The catalytic current is frequently much greater than the diffusion current. It may be used in different situations, such as catalytic cathodic stripping, catalytic ADSV, catalytic current polarography or catalytic hydrogen wave polarography.

Reviews of the environmental determination of inorganic species include fluoride,[18] organometallic compounds,[19] and total arsenic and arsenic compounds using EC methods.[20] Some inorganic methods included advanced electroanalytical techniques[21] and EC sensors.[22] The application of various electroanalytical techniques to environmental analysis has been reviewed.[23–25] The various techniques used include chronopotentiometric stripping,[26] voltammetry,[27] and polarography.[28] Many reviews on the environmental occurrence, properties, and determination of specific analytes have also been published. Voluminous reviews on environmentally significant metals have appeared in three volumes.[29–31] Other reviews have appeared on the electroanalytical determination of inorganic species in the environment,[32] and the chromatographic analysis of metals,[33] mercury and its compounds,[34] arsenic species,[35] organolead compounds,[36] cadmium,[37] and sulfur compounds.[38]

3 AIR ANALYSIS

The atmosphere is a protective blanket for the continuation of life on the earth; it is the source of carbon dioxide for plant photosynthesis and of oxygen for respiration. It provides the nitrogen that nitrogen-fixing bacteria and ammonia-manufacturing plants use to produce chemically bound nitrogen, an essential component of life molecules. As a basic part of the hydrological cycle the atmosphere transports water from the oceans to land. Unfortunately, the atmosphere has also been used as a dumping ground for many pollutant materials, ranging from sulfur dioxide to the refrigerant Freon which causes damage to vegetation and materials, shortens human life, and alters the characteristics of the atmosphere itself. The atmosphere absorbs most of the cosmic rays from outer space and protects organisms from their effect.

Protection of public health has long been an important force for the control of air pollution, beginning with the dramatic increases in daily deaths during the episodes of severe air pollution between 1930 and the early 1960s. Early measurements of air pollution in cities focused on two pollutants: sulfur dioxide and particulate matter. Present-day air quality control recognizes several

additional pollutants as potentially important to health, including oxidants and ozone, carbon monoxide, nitrogen oxides, lead, organics such as formaldehyde, and various aerosol constituents. Atmospheric aerosols are solid or liquid particles smaller than 100 μm in diameter. Pollutant particles in the 0.001–10-μm range are commonly suspended in the air near sources of pollution, such as the urban atmosphere, industrial plants, highways, and power plants. For the most part, aerosols consist of carbonaceous material, metal oxides and glasses, dissolved ionic species (electrolytes), and ionic solids. Some of the metals found predominantly as particulate matter in polluted atmospheres are known to be hazardous to human health. All of these except beryllium are so-called ''heavy metals''. Lead is the toxic metal of greatest concern in the urban atmosphere because it comes closest to being present at a toxic level; mercury ranks second. Others include beryllium, cadmium, chromium, vanadium, nickel, and arsenic.

3.1 Reviews and Monographs

A monograph covers several aspects of aerosol characterization.[39] The application of several microanalytical techniques for characterization of individual environmental particles has also been discussed.[40]

Stanley-Wood and Lines[41] edited a book on particle size analysis. Smoley[42] authored a text on methods of determining metals in environmental samples. Merian[30] published a review on the occurrence, analysis, and biological significance of metals in the environment. Other reviews dealt with electroanalytical methods for Zn, Cd, Se, and As,[23,24] procedures for determination of arsenic,[35,43] and determination of cadmium in biological and environmental samples.[31]

There are many reviews of analysis of atmospheric environmental samples ranging over seven major subcategories including sample collection, radon measurements, airborne microorganisms, site-specific assessments, methods of analysis, field instrumentation, and composition of aerosols.

The subject of collecting samples of air was reviewed with respect to particulate sampling technology,[44] consideration of sampling specifics for compliance to USOSHA (United States Occupational Safety and Health Administration) standards,[45] and sampling indoor atmospheres in workplace air monitoring.[46] Substantial interest has been shown in actual methods of analysis for indoor air monitoring of environmental carcinogens,[47] organic vapors,[48] and tracer gases for ventilation studies.[49] Noteworthy reviews from India[50] and from China[51] were used to describe modern instrumental methods of atmospheric pollution analysis for toxic compounds. Extensive coverage has been given to reviews of aerosols.[52–59] Especially relevant here is the review of chemical composition of aerosols[58] and trace elements in indoor/outdoor dust.[60]

Air monitoring is a global concern as shown by reviews of air pollution determination by gaseous and particulate sampling methods,[61] the state of environmental analytical chemistry and pollution climates in Europe,[62] and the monitoring of atmospheric pollutants from space.[63] Various combinations of filter media, extraction and analysis techniques used in the determination of inorganic species have been compared.[64]

3.2 Sample Collection

Sample collection is probably the most important step in trace analysis. Meaningful results will only be obtained if all risks of contamination are either minimized or eliminated. This, however is not an easy task.

Sampling of airborne matter was the topic of a review.[65] The use of diffusive samplers to assess community air pollution problems was also discussed.[66]

Kasahara et al.[67] described the optimum sampling conditions for analysis of atmospheric aerosols by particle-induced X-ray emission (PIXE) methods.

In order to obtain time resolution for aerosol composition, samplers have been developed that can deposit aerosol particles at different locations on the collection surface. These samplers are referred to as streakers. PIXE has sufficient sensitivity to be able to analyze a small quantity of deposited aerosol and PIXE multielement analysis has been applied to aerosol characterization in Milan,[68] Hungary,[69] and with cascade impactor sampling in Vienna.[70] In one work[71] air samples from Ankara were collected on glass-fiber filters and were analyzed by differential pulse polarography (DPP).

3.3 Techniques

DPP has been successively applied to the determination of copper, lead, cadmium, zinc and titanium in air particulates.[71] Air samples were collected on glass-fiber filters and acid digested prior to analysis. Using EDTA (ethylenediamine tetraacetic acid)–sodium acetate electrolyte at pH 2.0, it was possible to determine all five metals in a single polarographic scan.

Stripping voltammetry has been used for the determination of trace metals in particulate matter. DPASV was used to determine Cd, Pb, Cu and Zn, while the detection of Se required differential pulse cathodic stripping voltammetry (DPCSV).[72] An HMDE was used with both stripping methods. The only sample pretreatment required was filtration through a filter to remove the coarse particulate matter and adjustment of the filtrate to

pH 2.0 with HCl. Trace metals bound to the airborne dust particles were determined by subjecting the collected particles, together with the filter media, to low-temperature ashing. In this way, the metal ions contained in the organic layer on the surface of the dust particles were digested completely and were accessible to subsequent DPASV measurement.

Adsorptive CSV has been applied to determinations of Cu, Cd, Ni, and Co in atmospheric samples.[73] For determination of Pb and Cd, samples were collected on glass-fiber filters and were analyzed by DPASV.[74]

For the trace metal determination of Pb and Cd, stripping voltammetry and measurements based on ion selective electrodes were used.[75] A review of EC sensors for monitoring environmental pollutants[76] presents a survey of advances in EC sensor technology which have attempted to improve the performance of these devices. Three main areas of development have been addressed: advances in sensor design and measurement techniques, novel approaches to increasing electrode selectivity and the use of microminiaturization and microelectronics fabrication techniques. An improved voltammetric procedure has been developed[77] for determination of Zn, Cd, Pb, and Cu.

3.4 Sources

The existence of metals in the environment is a result of both natural and artificial processes. Lithogenic origins, e.g. ore deposits and volcanoes, were the predominant sources of metal before the Industrial Revolution. However, the present-day levels of heavy metals in the environment are almost exclusively from anthropogenic sources.[78] These metals are released into the environment either directly by wastewater discharges and run-off, or indirectly via the atmosphere adsorbed onto precipitates and dust. Owing to the ubiquity of heavy metals in the environment, they can become incorporated in food chains and drinking water, eventually being taken up by humans.

Among the most hazardous heavy metals are Cd, Pb and Hg. These three metals are toxic at all concentrations and have no biological function.[79] A second group of metals, containing As, Bi, In, Sb and Tl, have no biochemical requirement by man and are only tolerated at trace levels in biochemical systems. Finally, there is a third group of metals which are known to be biochemically essential. Among these essential elements are Cu, Zn, Co, Ni, V, Se, Cr and Fe. Even this last group of metals, though essential below their respective threshold levels, become progressively toxic above certain levels. Some of these metals, e.g. Ni, Cr, Cu and Se, are known to display carcinogenic effects[80] due to their interaction with nucleic acids.

In general, the toxicity of metals stems from the fact that they are biologically nondegradable and have a tendency to accumulate in vital organs, e.g. brain, liver or bones of humans, and by their accumulation become progressively more toxic.[81,82] However, the degree of toxicity exerted on a biological system depends on the chemical form or oxidation state of the particular heavy metal. For example, studies have revealed that ionic copper is far more toxic towards aquatic organisms than copper bound by organic ligands, and that the more stable the copper complex, the lower is its toxicity.[83,84] It is also known that As(III) is much more toxic than As(V).[85]

Perhaps the most insidious forms of heavy metals are their alkylated derivatives. Many of such compounds, e.g. alkylleads and alkyltins, have been found in environmental samples.[86] Apart from anthropogenic sources, some of these compounds are produced naturally by chemical[87,88] or biological processes.[89,90] Consequently, many heavy metals released into the environment can become even more toxic once transformed to their alkylated forms. In particular, the alkyl compounds of mercury and lead are especially toxic because they are lipid-soluble.[91] Generally, the toxicity of alkylated species tends to increase with the degree of alkyl substitution and carbon chain length of the alkyl group.[86]

3.4.1 Fixed Sources

In the category of fixed or stationary sources of airborne environmental pollutants, a broad range of types and kinds of source encompasses industrial to natural sources such as minerals, soils, waters, some plants and volcanic eruptions. Industrial and fugitive emissions, incinerators, stacks, residues and nuclear plants are among the fixed sources of airborne pollutants. Municipal incinerators are those in which the fuel or feedstock principally originates from domestic waste including paper, wood, kitchen scraps, and so forth. In contrast to the strong interest in organic compounds found in emissions from municipal incinerators, few reports have been found on the subject of metals, especially toxic metals, in the flue gases from such incinerators. The interest in metals in such effluent or flue gases is restricted to mercury, hexavalent chromium, arsenic, gallium, lead and selenium.[92–95] The trace metals in emissions from coal-fired incinerators can be determined by AAS, NAA, PIXE as well as by electroanalytical methods.

3.4.2 Mobile Sources

Mobile sources, particularly vehicles with internal combustion engines, have been examined since the 1970s for the chemical composition of their exhausts. Various mobile sources were targeted for chemical characterization of airborne pollutants and these included exhausts

from combustion-based engines with gasoline[96,97] and with diesel fuels,[98–100] jet craft engines,[101] and cigarettes.[102,103] Cigarettes can also be regarded as a type of mobile airborne pollutant source both outdoors and indoors. Tobacco smoke condensates were analyzed (as an indoor pollutant) for metals such as As, Cd, and Pb[101] at toxicologically relevant concentrations and for Se.[102]

3.4.3 Ambient Air

Analysis of air in urban and industrial settings for inorganics,[104,105] principally metals, has been accomplished using several techniques such as PIXE, X-ray fluorescence measurement, NAA and also electroanalytical techniques. The sampling method of choice for practical applications was high-volume filtering of air with trapping of particles which are later analyzed. A comparatively high level of interest was taken in metal determination in nonurban or natural locations. Examples are analyses of marine aerosols for Ti, Cr, Fe, and Ni,[106] and determination of transition metals in aerosols at the Brazilian Antarctic Station and at a biomass burning site in the Amazon basin.[107] Other examples include determinations of metal ions in the auroral lower E-region[108] and of atmospheric aluminum in the air at the French Riviera compared with determinations of Pb, Cd, Cu and Zn in Saharan dust.[109] Zn, Cd, Pb and Cu ions in ambient air can be determined by ASV.[77]

3.5 Accidents and Emergencies

Air monitoring during accidents or emergencies has received little attention, presumably due to the unplanned or unscheduled nature of an emergency and the speed at which events can overtake systematic sampling and analysis. The fallout and environmental poisoning from the Chernobyl nuclear facility figured prominently in terms of ^{235}U in soil particles as a source of dust,[110] and of ^{90}Sr in air filters in the late postaccident period using gamma spectroscopy.[111]

Vehicle fires in traffic tunnels, a special type of emergency, were considered in terms of sampling strategies with a mixture of passive and active collectors.[112]

3.6 Atmospheric Chemistry, Transport and Deposition

Wet deposition includes the collection of airborne pollutants in condensed rather than vapor form within rain drops, snow, or liquid aerosols (fog).

Davidson[113] discusses the mechanisms of wet and dry deposition on snow. The determination of heavy metals is complicated by adsorption on the collection funnel walls[114] and by contamination of Cd and Zn from metal surfaces.[115] Programs and analytical methods for rainwater monitoring have been developed.[116,117]

Ultratrace determinations of heavy metals can be carried out in rainwater[118] and in snow and ice.[119]

4 WATER ANALYSIS

Throughout history, the quality of drinking water has been a factor in determining human welfare. Currently, waterborne toxic chemicals pose the greatest threat to the safety of water supplies in industrialized nations. The quality of groundwater is subject to a number of chemical influences. There are many possible sources of chemical contamination of water. These include wastes from industrial chemical production, metal plating operations, and pesticide runoff from agricultural lands. Some specific pollutants include industrial chemicals such as chlorinated hydrocarbons, heavy metals (including cadmium, lead and mercury), saline water, bacteria and general municipal and industrial wastes. Since World War II there has been a tremendous growth in the manufacture and use of synthetic chemicals. Many of the chemicals used or manufactured by industry have contaminated water supplies. Water pollution should be a concern of every citizen. Understanding the sources, interactions, and effects of water pollutants is essential for controlling pollutants in an environmentally safe and economically acceptable manner.

Some of the heavy metals are significant water pollutants. Cadmium, copper, lead and mercury ions bind to cell membranes, hindering transport processes through the cell wall. Heavy metals may also precipitate phosphate-containing biochemicals or catalyze their decomposition. Some of the metalloids, arsenic, selenium, and antimony, are also known as significant pollutants. Manufacture of inorganic chemicals has the potential to contaminate water with trace elements. Among the industries regulated for potential trace element pollution of water are those producing sodium dichromate, chlor-alkali, hydrofluoric acid, aluminum fluoride, chrome pigments, copper sulfate, nickel sulfate, sodium bisulfate, sodium bisulfite, sodium hydrosulfate, titanium dioxide, hydrogen cyanide and various plating industries.

4.1 Reviews and Monographs

There are an increasing number of articles appearing in the literature describing the analysis of trace pollutants in environmental waters. Toxicity data for many hazardous compounds were compiled by the European Chemical Industry Ecology and Toxicology Centre selection criteria and the structure of this database and its uses have been described.[120] Soluble filters can be used for preconcentration of trace elements in water.[121] Contamination in the course of analysis of trace metals can

be minimized.[122] Other topics discussed are instrumentation and automation used in wastewater treatment,[123] pollutant monitoring and determination,[124] as well as analytical methods for the determination of trace components.[125] Analytical techniques, as applied to water analysis, including in situ voltammetric measurements, were described in a review containing 154 references.[126]

4.2 Sample Collection

Sample collection is a very important step in determination of traces of metals in water. The first problem is to choose the type of sampling bottle that will be used. When the often preferred high-pressure (low-density) polyethylene bottles are used,[127] they should be degreased and leached by an acid to remove trace metals present.[127] Alternatively, Teflon™ bottles may be used as this is the only material that does not release zinc into a water sample.[128] Surface water samples taken in the open ocean cannot be taken directly from a large ship because the ship is continually releasing copper, lead and zinc from its antifouling paints and cathodic protection devices.[129] In such situations, the only safe way to sample is to use a small rubber dinghy which is rowed to the sampling site. Sampling is undertaken at the bow of the boat whilst slowly rowing into the wind to prevent contamination of the sampled water by the boat.[130] Collection of surface samples from coastal waters, estuaries, rivers and lakes is usually undertaken from small boats using a telescopic bar with an attached sample bottle.[127]

For the collection of samples at depths greater than 10 m the aforementioned methods are unsuitable. The normal procedure involves clamping a sampler to a hydro wire and lowering the sampler to the required sampling depth. However, this method is prone to sample contamination by rust and grease from the hydro wire.[131] This procedure can introduce a large amount of trace metal contamination, especially lead. These contamination problems can be circumvented by using the all-Teflon™ Patterson CIT sampler.[132] This is one of the few sampling devices that can collect deep seawater samples without metal contamination.

4.2.1 Storage of Water Samples

Storage methods employed depend on the nature of the measurements which are to be undertaken. For speciation studies, water samples should not be acidified as this would change the nature of the speciation.[133] Likewise, freezing of water samples is not possible. As a water sample freezes, metal ions are concentrated in the unfrozen liquid in the center of the container, where they may undergo chemical and physical alteration.[129] Thus, samples for speciation studies should be filtered through a 0.45-μm membrane filter to remove any suspended material. The filtrate, containing the dissolved heavy metal fraction, should subsequently be stored at 4 °C, as this appears to be the safest method for both freshwater and seawater samples.[134,135] Storage of samples at higher temperatures may result in speciation changes. This has been observed for cobalt and manganese when water samples were stored at room temperature.[136] Changes induced by a pH drop due to bacterial respiration, in which oxygen was consumed and carbon dioxide was released, resulted in precipitation of cobalt and manganese carbonates.

If the total concentration of dissolved heavy metals is to be determined in a water sample, then the filtered sample is usually adjusted to pH 2.0 by adding a small amount ($1\,mL\,L^{-1}$) of concentrated hydrochloric acid or perchloric acid.[6] Acidification of the sample helps prevent loss of metal by adsorption on the walls of the storage container. However, in some instances, acidification may cause leaching of metals, especially lead and zinc from the container walls.[127] The best method of sample storage is freezing to −20 °C or at liquid nitrogen temperature.[137] This eliminates leaching of trace metals from the container and also losses by adsorption.

When filtered samples are stored at room temperature for less than a week, acidification is unnecessary.[138] In the case of long-term storage, filtered samples, whether acidified to pH 2.0 or unacidified, have to be deep frozen.[138]

4.3 Techniques

Polarographic and voltammetric methods are mostly used in water analysis. Among the polarographic methods the most sensitive direct method of analysis is DPP. It has been used to determine the total chromium content of a river water sample.[139] Before DP polarographic analysis, all chromium present in the water sample was converted to Cr(VI) by oxidation with H_2O_2 followed by determination in 1 M NaOH. The result was to be in good agreement with that obtained by flame AAS.

Direct determination of As(III) and Pb(II) in the run-off water from waste disposal grounds has also been accomplished by DPP.[140] The sample pretreatment simply consisted of addition of a supporting electrolyte (2 M NaCl and 2 M H_2SO_4) followed by deaeration and recording the DP polarogram at a DME. The complete analysis took 20 min to perform. A high sulfuric acid content was required to ensure sufficient separation of the responses of Pb(II) and As(III). If As(V) is present, it must first be reduced to As(III) using hydrazine, before it can be determined. With this method, determination limits of $40\,\mu g\,L^{-1}$ or less are attainable. Generally,

direct determinations are only possible when the metal concentrations are sufficiently high. For example, the detection limit for cadmium in water matrices is $10\,\mu g\,L^{-1}$ when DPP is used.[141]

When surface active organic traces are present, the detection limit is restricted to higher concentrations. For the determination of ultratrace levels of metals, stripping voltammetry is required. The voltammetric mode most frequently used for the determination of metals at such ultratrace levels is DPASV. This method has been successfully applied for the determination of trace metals in rainwater, seawater, freshwater, saline water and snow samples. Ni and Co can be simultaneously determined in rainwater samples.[8,9] ASV, CSV and adsorptive stripping voltammetric methods are also among the most frequently used methods.[142–150]

Many new procedures for trace analyses include determinations of iron,[142] aluminum,[143] zinc,[144] platinum,[145] molybdenum,[146] copper,[147] titanium,[148] nickel and cobalt,[149] and cadmium, lead and copper,[150] in seawater,[142,143,144–150] rainwater[148] and river water[149] by using some chelating agents.

A development in environmental analysis has been the construction of on-line sensors for trace metals based on stripping analysis.[151] An automatic voltammetric analyzer for the determination of four trace metals (Cd, Pb, Cu and Zn) in water has been developed.[152] This analyzer was employed for the intermittent on-line analysis of tapwater supplied by water works, although it can also be applied to the analysis of wastewater samples. With this device, samples are automatically taken from the mains water supply, acidified and analyzed by DPASV at an HMDE. Each sample solution is analyzed twice followed by two standard additions for calibration purposes. The detection limit is $0.1\,\mu g\,L^{-1}$.

Another form of automated system is a flow injection analysis (FIA) using ASV for detection.[153] In this type of system, small volumes of sample solution are injected into a carrier stream, which transports them towards the detector. Deposition occurs while the sample is flowing through the detector and the stripping step is effected after the sample volume has passed the detector. The most commonly used electrodes are the HMDE and MFE. Solid gold electrodes are used for monitoring metals with oxidation potentials more positive than that of mercury.[154] The stripping mode utilized depends on the analyte concentration. The linear mode is used to monitor in the $5–50\,\mu g\,L^{-1}$ concentration range. In this concentration range, short deposition periods (1–3 min) are employed so that the analysis takes 2–4 min, which means that carrying out 15–30 measurements per hour is possible. At lower concentrations the DP mode is used, but this considerably lengthens the time of each analysis, given the slow scan rate ($2–5\,mV\,s^{-1}$) in the stripping stage. An automated ASV flow system, based on a mercury-coated graphite tubular electrode, has been applied to the continuous monitoring of copper and zinc in marine environments.[155]

Another type of a flow-through detection system for the determination of trace metals involves combining high-performance liquid chromatography (HPLC) with EC detection. An example of such an approach is the selective determination of copper in tapwater using reversed-phase HPLC.[156] It involves complexation of copper with dithiocarbamate (DTC) ligands. The preferred method for formation of the $Cu(DTC)_2$ complex was inclusion of a DTC salt in the mobile phase and injection of the aqueous sample onto the column to form the complex in situ. Determination of the copper complex, using the oxidative process, was undertaken at a gold electrode. The DC response of the electrode was monitored at +0.6 V. The results by this HPLC/EC detection method were compared with those obtained by AAS, and excellent agreement has been found for results obtained by these two methods. The use of HPLC with EC detection has also been extended to multielement determinations. By forming diethyldithiocarbamate complexes of Cu, Ni, Cr and Co it was possible to determine simultaneously all four metals.[157] When pyrrolidine DTC was used as the complexing ligand, Cd, Cu, Co, Pb, Hg and Ni were determined.[158]

Other electroanalytical methods used in trace metal analysis include anodic stripping coulometry[159] and (chrono)potentiometric stripping analysis (PSA),[160,161] which is a relatively new analytical method, but resembles voltammetric stripping analysis by involving two discrete steps. In the first step, the analytes are deposited at or dissolved in a suitable electrode by application of an appropriate potential. In the second step, the preconcentrated analyte is stripped at a constant or zero current and change in the potential of the working electrode is recorded as a function of time. Both oxidative and reductive PSA methods have now been developed.[162] The APASA on-line analyzer by Tacussel is designed for control in water processing plants. It automatically performs on-line polarographic determination of trace amounts of Ni, Zn, Cd, Pb, Cu and Cr in primary waters of rivers, estuaries, seawater and so on. A built-in ultraviolet mineralization stage allows the system to treat waters loaded with organic material directly. The water is filtered before being pumped into the EC system for final sample preparation and analysis. Metrohm has recently marketed an automatic VA Trace Analyser that incorporates an autosampler.

4.4 Sources

The role of surface waters, rivers and lakes as pollutant transporters, as well as analyses of groundwater, drinking

water, seawater, municipal wastewater and industrial wastewater will be discussed in this section.

4.4.1 Surface Water, Rivers and Lakes

Interest in surface waters has increased, and this trend reflects an increased awareness of the importance of lakes and rivers in the transport of pollutants. Inorganic analytes were studied most often. Examples are the use of DPP in determination of the total chromium content of river water[139] or that of DPASV for a simultaneous determination of Tl(I) and $(CH_3)_2Tl(I)$ ionic species in buffered lake water samples with estimated detection limits of 3.2 ppb and 3.4 ppb, respectively.[163] Since the consequences of mixing organothallium compounds with mercury salts were unknown, the plating of a thin mercury film on a GCE was performed separately from the sample deposition step, rather than using in situ film deposition and compound accumulation. The other heavy metal ions such as Pb(II), Zn(II) and Cd(II) interfere in the determination of the thallium species, so that an addition of EDTA is necessary, which results in a slight shift of the peak potentials to more negative values and in a decrease in the peak current due to Tl(I) ion. One of the simplest procedures based on an ASV measurement has been developed for the speciation of copper in river water.[164] In this scheme samples of water were adjusted to pH 8.0 and the copper content measured by DPASV. Following this step the sample was acidified to pH 2.0 and the copper concentration was again determined. There was a tenfold increase in the measurable copper concentration on decreasing the pH of the water sample. The smaller stripping current at high pH was attributed to the nonlabile nature of the copper species present. The nickel and cobalt level of the surface water of the Mediterranean Sea was determined by adsorptive cathodic stripping square-wave voltammetry.[165] The concentration of the dissolved cobalt ions in the surface water was 0.168 nM but it decreased to 0.045 nM at a depth of about 300 m.

4.4.2 Groundwater

Two reviews[166,167] and a monograph covering the problem of groundwater contamination[168] have been published. Some other reports have described the monitoring program at Savannah River,[169] the quality control program at Hanford,[170] and an overview of statistical methods for groundwater monitoring.[171] Monitoring data from 500 waste disposal sites showed that volatile organic compounds are the most abundant class of organic contaminants in groundwater. Adsorptive catalytic stripping voltammetry was used for the determination of total chromium in groundwater with a detection limit of 1 ppt.[172] DPP and differential pulse catalytic adsorptive stripping voltammetry (DPCASV) techniques were used for the speciation analysis of organic and inorganic Se compounds in natural waters. The detection limit was $10\,\mu g\,L^{-1}$ in the DPP analysis and $0.04\,\mu g\,L^{-1}$ in the DPCASV analysis.[173]

4.4.3 Drinking Water

Contamination of drinking water and the natural environment by toxic metals is a serious problem. In the USA alone there are over 30 000 abandoned chemical dump sites, many of which are leaking various pollutants into sources of local waters. This provides a strong incentive for the development of continuous metal analyzers. Monitoring of drinking water is demanding since the permissible metal levels are very low, generally at parts per billion levels (US Environmental Protection Agency recommended standards are Pb 0.005 ppm and Cu 0.02 ppm). Using a portable (chrono) potentiometric stripping analyzer, Cu(II) at 0.1–5 ppm and Pb(II) at 1–50 ppb could be detected in a 0.4-mL drinking water sample.[174]

4.4.4 Seawater

Great interest has been shown in the analysis of seawater, as reflected by the development of new methods for the determination of inorganic species. Speciation studies of Cu and Ni use competitive ligand equilibration CSV, DPASV and graphite furnace AAS.[175] Mercury is determined by ASV with a GCE spin coated with a hexacosane derivative.[176] Arsenic is determined by CSV.[177]

A particularly important area of study is the quantification of dissolved metal species in both freshwater and seawater samples. Electroanalytical determination of the dissolved metal content in these samples requires a limited sample pretreatment, which minimizes error sources arising from contamination. The usual procedure involves sample filtration through a 0.45-μm filter to remove particulate matter present and acidification of the filtrate to pH 2.0 with concentrated HCl. Samples are usually left to stand for several hours to allow the completion of decomposition of most complexes present. The metal ions Cu, Cd and Pb are then simultaneously determined by DPASV at an MFE, with the possibility of determining these three metals to levels as low as $1\,ng\,L^{-1}$.[178] Because of the lower hydrogen overvoltage of the MFE, less negative plating potentials of −1.0 V are applied in media at pH 2.0. Hence, zinc which is reduced at more negative potentials has to be determined separately at pH 4.5.[6]

ASV is especially suited for the analysis of seawater and other saline waters because the high-salt matrix

provides excellent conductivity, whereas it is a source of interference in AAS.[179] DPASV was employed for the simultaneous determination of Zn, Cd, Pb, Cu, Bi(II) and Sb(III) in different matrices such as seawater,[180,181] suspended particulate matter and plankton[182] at the microgram per liter level. A routine speciation method was also proposed[181] in a pollution survey of coastal seawater. A combination of DPASV at an HMDE and linear ASV was used with collection at a rotating ring disc electrode (RRDE) for identification of soluble Zn, Cd, Pb, Cu, Bi and Sb trace metal species. A limit of detection between 0.005 and 0.25 mg L^{-1} was obtained for antimony determination. A simple method that allows Sb(III) and Sb(V) to be determined selectively is based on CSV after accumulation as amalgam from hydrochloric acid solutions.[183] The disadvantage of this simple method is the interference of bismuth and copper. It is possible to determine dissolved antimony as well as Sb(III) in freshwater and seawater by CSV[184] in the presence of catechol with a detection limit for Sb of 0.16 nmol L^{-1}. Alternatively it is possible to differentiate antimony oxidation states using ADSV[185] with chloranilic acid as a complexing agent. Spiked seawater samples were analyzed and detection limits of 210 ng L^{-1} for Sb(III) with 5 min preconcentration and 560 ng L^{-1} for Sb(V) with 10 min preconcentration were reported. Another study revealed that antimony could be accumulated in the presence of triphenylmethane dyes[186] in order to develop more sensitive and selective methods for antimony speciation. Automated constant-current stripping analysis for Sb(III) and Sb(V) with gold-fiber working electrodes enabled analyses of river and seawater reference samples at microgram per liter levels.[187] DPASV using an MFE has been employed to determine the levels of dissolved Cd, Pb and Cu in coastal and inland waters.[188] This study revealed that Cd and Pb levels were usually elevated along main shipping routes, while in the immediate vicinity of these routes the levels dropped abruptly to the values of the local coastal waters. It was also found that areas where the water is rich in suspended particulate matter tended to have low dissolved metal concentrations, typically 5 ng L^{-1} Cd, 18 ng L^{-1} Pb and 130 ng L^{-1} Cu. This is related to the high metal uptake by plankton organisms and/or metal trapping due to chemisorption at suspended inorganic and dead organic matter surfaces.

A recent survey used DPASV at an MFE to determine total and dissolved concentrations of Cd distributed in coastal and open ocean waters.[189] This survey found that coastal waters contained higher cadmium concentrations than open ocean waters. Generally, cadmium was preferentially present in the dissolved state, although in heavily polluted waters with large amounts of suspended particulate matter, the total levels were higher than the dissolved contents. Because Cd was present preferentially in the dissolved state, it was suggested that it can be used as a suitable tracer when studying the movement of pollution plumes in coastal waters.

Another toxic metal frequently found in the environment is mercury. A method has been developed for the determination of mercury in water samples, after acidification of the sample to pH 1.0, by DPASV at an activated gold electrode.[190] The detection limit of the method was 50 ng L^{-1}. This method was found to be suitable for the simultaneous determination of copper and mercury. Furthermore, for high levels of copper, the gold electrode is more suitable than the mercury electrode, because problems associated with the limited solubility of copper as an amalgam in mercury are eliminated. For the determination of copper in seawater, medium exchange after the plating stage was necessary. This was required because the response corresponding to chloride oxidation interferes, and the chloride formed would damage the surface of the gold electrode. For the determination of ultratrace levels, below 30 to 50 ng L^{-1} in seawater, a method based on DPASV in the subtractive mode at a twin gold electrode was recommended.[191] The separation of the two halves of the gold disc by an insulating epoxy resin allows application of different potentials to both halves. Operation of the subtractive mode ensures a low background current. There was good correlation between results obtained by this method and those by cold vapor AAS. However, as the voltammetric response is complicated, it was suggested that for routine ultratrace determinations of Hg the application of cold vapor AAS was more convenient.

The voltammetric determination of mercury in seawater has been improved by using an epoxy resin-cast gold disc electrode,[192] which allows extremely low concentrations of the toxic metal to be detected (2 ng L^{-1}). Seawater samples collected off the Swedish coast in both the Baltic and North Seas were analyzed by DPASV with a gold disc electrode, yielding mercury concentrations of 8.8 and 7.0 ng L^{-1}, respectively, with a precision of about ±20%.

Adsorptive CSV has been applied for the determination of many trace elements in seawater. A review including 51 references by Van Den Berg[193] discussed the applications of this technique to analysis of seawater. The preconcentration step in this method can consist of precipitation of an insoluble salt, or adsorption of a surface-active complex, prior to the reduction of the deposited material. The former method gives an irreversible reduction current, and is therefore not very sensitive to low concentrations of trace elements. The latter procedure results in the formation of a monolayer of complexed species at the surface of the mercury electrode, which is reduced reversibly and completely, yielding a high sensitivity. A variety of ligands have been used to

form adsorptive complexes useful for the determination of trace elements in seawater. Among them catechol was found suitable for the determination of Cu, Fe, Sb, Sn, V at pH levels of 6 to 8,[194–196] DMG was used for the determination of Co, Ni and Pd at pH 8–10,[197] nioxime for that of Co at pH 7.5,[198] quinolin-8-ol for Cd, Cu, Mo, Pb and U at pH 7–9,[199] diethylenetriaminepentaacetic acid (DTPA) for Cr,[200] mandelic acid (MA) for Ti at pH of 3.0[201] and tropolone for Mo and Sn at pH 2.0[202] in seawater samples. In these procedures the reduction of the metal ion from the adsorbed complex took place in the stripping phase. Platinum in seawater was determined by the catalytic current of hydrogen evolution in 0.5 M sulfuric acid medium.[203] The total tin in estuarine waters was determined by adsorptive CSV using tropolone[204] as the complexing ligand. A deposition potential of −0.8 V and a reoxidation potential of −0.4 V were used. Starting at the latter, the current–voltage was next recorded toward more negative potentials. Samples had to be ultraviolet photolyzed prior to analysis in order to remove interfering surface-active organic compounds. The limit of detection was 5 pM tin using a 10-min stirred deposition prior to the scan.

The total tin content in the shipyard water was determined by DPP.[205] A 100-mL sample solution was evaporated until 5–7 mL remained, then Sn(II) was oxidized in acidic solution with H_2O_2 to Sn(IV). In an EDTA solution at pH 5 the interference of lead could be eliminated and tin level of the water was found to be 1.2×10^{-6} M. For the simultaneous determination of Co and Ni in seawater, adsorptive cathodic stripping square-wave voltammetry has been applied.[165] Here the complexes of cobalt and nickel with DMG are analyzed by a voltammetric method based on adsorptive collection at an HMDE. This method had greater sensitivity than the DPCSV method and a faster scan rate. At pH 8.0, with an adsorption potential of −0.7 V and adsorption time of 60–180 s, depending on the concentration of cobalt and nickel in the sample, and a scan rate of 140 mV s^{-1}, detection limits for cobalt and nickel were obtained at approximately 8 pM and 0.05 pM, respectively.

The accuracy of the method for the determination of Bi(III) in seawater at its natural pH of 8.1[206] is similar to those previously reported for strongly acidified samples.[207] This method employs the square-wave mode for the anodic potential scanning at a bare glassy carbon rotating-disc electrode instead of at a mercury-plated one. In seawater, the GCE is highly selective for bismuth in the presence of the other commonly found metal ions; only Cu(II) reacts, but bismuth can be determined even in the presence of a 100-fold concentration of Cu(II) by selecting an appropriate accumulation potential. This method is sensitive to bismuth ions (including hydrated Bi(III), oxy- and hydroxy-species and various labile complexes) and not to its total concentration. The bismuth content in a sample collected near the coast of Heligoland was found to be 12 ± 2 ng L^{-1}. The newly developed PSA method has been used for the determination of Pb, Cd and Zn in seawater using an MFE.[208]

4.4.5 Municipal Wastewater

Inorganic species of concern included Pb and Cd and free available chlorine and total residual chlorine. Several commercial instruments designed for field analysis of toxic metals have been introduced. A portable, semi on-line voltammetric analyzer developed by Chemtronics uses a glassy carbon working electrode, operates on 0.1–5-mL batch samples and provides automatic deaeration and system calibration. Targeted at industrial effluent and domestic water supply analysis, measurable metals include Sb, As, Bi, Cd, Cu, Au, Pb, Hg, Tl, and Zn over the concentration range down to 10 ppb.

4.4.6 Industrial Wastewaters

Studies on the analyses or composition of wastewaters from industry or the other facilities such as governmental laboratories can be divided conveniently into categories by product or activity. The pulp and paper industries, miscellaneous manufacturing industries, chemical industries, and plating or tannery and dye manufacture industries are the main sources of inorganic species causing water pollution. As the contamination of the natural environment by toxic metals is important, all water runoffs have to be monitored for many of the major pollutants. This is providing a strong incentive for the development of continuous metal analyzers. The other major incentive is the need to monitor effluents from existing waste generators such as electroplating plants, manufacturers of electronics products and some mining operations. In these applications two types of analytical measurement are generally required. In the first, monitoring of the performance of waste treatment equipment is carried out to detect a malfunction, for example saturation of an ion-exchange column. The second type of measurement is an end-of-pipe analysis to ensure that the plant discharge meets compliance. In the former case, fairly simple metal monitors which can provide an alarm response in the range 5–20 ppm are adequate whereas the requirements for discharge monitoring are much more rigorous. These may be required to indicate compliance with the local discharge standards which in California, for example, are 0.1 ppm for Pb and 0.5 ppm for Cu. Trace metals in wastewater streams are also routinely determined for wastewater management. The concentrations of the metals can vary considerably as a function of time because of the level and type of activity at the generating source. Thus on-line, near real-time measurement capabilities are highly

desirable. An example is an on-line voltammetric analyzer for trace metals in wastewater.[209] By this device, Cr, Ni, Zn, Cd, Pb and Cu were determined automatically with detection limits close to 50 $\mu g\,L^{-1}$ to characterize a wastewater stream.

For automated trace metal analysis on-line ASV is now the technique of choice. In the last few years there have been some major advances in cell design, instrumentation and control systems. An improved version of the wall-jet cell using microprocessor control has been used in continuous flow ASV,[210] while a similar approach using a thin-layer cell and flow injection has also been described.[211] Eutech Cybernetics[210] has developed a hand-held metal monitor, also based on the ASV principle. A novel feature of this system is the use of disposable electrode strips on which the electrodes have been screen printed. Designed as a dedicated metal monitor for copper or lead, each unit has high and low operating ranges: 0.01–0.7 ppm and 0.5–3.0 ppm. The main application of the Electrascan[210] is also for monitoring of drinking water and of industrial effluents. The use of disposable electrodes, as was discussed earlier, has some significant advantages including elimination of the need for electrode preconditioning which is a tedious feature of most stripping voltammetric methods. It also avoids problems of cross-contamination of samples which may occur in continuous flow systems. A two-point calibration is first carried out using one of the two electrodes in the Electrascan sample chamber, using calibrating standards. Next, one drop of the activating solution is added to a 1.0-mL sample, then a 100-μL aliquot is introduced into the cell chamber. The analysis is completed and the result displayed in approximately 100 s. Improvement in the design and fabrication of the DME by Novotny and Heyrovski[212] has provided a much more robust, versatile sensor with wide ranging applications in environmental monitoring. Potentiometry was used to determine Hg(II) in chloralkali effluents.[213]

5 SOIL AND SEDIMENT ANALYSIS

Metals are released into the environment either directly by wastewater discharges and runoff, or indirectly via the atmosphere adsorbed to precipitates and dust. Because of the large quantities of heavy metals in the environment, they can become incorporated in food chains and drinking water, eventually being taken up by humans. The lead content of roadside soil has been found to vary between 100 and 3000 ppm, depending on the location and the volume of traffic. In contrast, the average lead content of the earth's crust is about 16 ppm. Marten and Hammond[214] investigated three types of soil samples and found that samples near a battery smelter, near a road, and from a greenhouse contained 680, 59, and 12 ppm of lead, respectively. Most of the lead in soil exists in sparingly soluble forms. When 2784 ppm of lead nitrate were added to soil, it was found that after three days the soluble lead content was only 17 ppm. It is to be expected that all ions in nature will accumulate as their less soluble compounds, such as oxides, carbonates, silicates and sulfates, the relative proportions of each depending on the nature of the soil and on the solubility.

Meat, seafood, milk, eggs and many other foods are sources of many toxic elements. The amount of these elements is influenced by the element content of the soil. The minerals move from the soil to the plants that grow on it, then to the animals that eat plants. The concentration of selenium in human milk samples obtained from vegetarian women was significantly greater (22 $ng\,mL^{-1}$) than from nonvegetarian women (16 $ng\,mL^{-1}$).[215] The milk samples obtained from a farm which was near to a road supporting heavy traffic contained 60 $\mu g\,L^{-1}$ lead, whereas 22 $\mu g\,L^{-1}$ of lead was normally expected.[216]

5.1 Reviews

Although considerable work on the determination of metals in soils and sediments has been reported, most studies represent small improvements in the application of existing methodology rather than novel analytical approaches. In a natural aquatic environment heavy metals will be deposited in the surface layers of sediments. Although sediments contain the greatest concentration of metals, only a few studies on the speciation of heavy metals in sediments have been undertaken.[217] Chemometric techniques can be used to investigate to what extent soil sampling presents a representative picture of soil as a whole.[218] Three methods of fluvial sediment sampling were studied to determine how valid and representative is the geochemical information obtained from each technique.[219] Bottom sediments and trap sediments showed similar results for metals. Methods for the determination of heavy metals in soils and sediments were reported in many studies. The chemical speciation and environmental mobility of heavy metals were reviewed by Sager.[220] An interlaboratory study where the extraction techniques were specified but the measurement method was optional showed a strongly differing degree of comparability for the various elements, extraction techniques, and measurement techniques used by the different laboratories.[221] In other studies, the use of an ultrasonic slurry sampler[222] and the recovery efficiencies of heavy metals during acid digestion by different acid mixtures and by block heater and microwave heating[223] were reported. Developments in the analysis of estuarine and coastal sediments for heavy metals have been

reviewed.[224] Methods have also been developed for specific metals in soils and sediments.[225,226]

5.2 Sampling

Problems associated with techniques and strategies of soil sampling[227] and with the collection and preparation of soil samples for the Federal Soil Survey Laboratory Program have been reviewed.[228] Various sampling schemes for soils have been described.[229,230] Different sampling designs are needed, depending upon whether the soil contamination is expected to be ''spread'' over the whole area or exists in localized ''hot spots''.[231] A decision-support system for the sampling of aquatic sediments in lakes was described by Wehrens et al. and was applied to a real environmental problem.[229] Lame and Defize showed that the fundamental sampling error for soils affects the analytical variance only when sample sizes are less than 10 g.[230] For larger samples, the variance is determined by the segregation error. A sampling board method for estimation of the segregation error was described. A two-way compositing strategy can be used to attribute detected contamination in composited samples directly to constituent samples without further analyses.[232]

Evaluation of various soil and sediment samplers has been reported.[233,234] The sediment shovel proved highly practical, but was limited because small particles tend to be lost when the shovel is lifted.[233] A cryogenic sediment sampler was less convenient to use, but allowed the collection of nearly undisturbed samples. Another device has been suggested for the automatic subsampling of soil, sediment and plant material for proficiency testing.[234] In another study, freeze-sampling collects representative sediment samples, whereas grab-sampling introduces a bias in the textural composition of the 120-mesh fraction, caused by washout and elutriation of the finer fractions.[235]

5.2.1 Sample Preparation

The risks of sample contamination using inappropriate materials, containers and tools, as well as possible analyte loss during sample handling, have been discussed.[236] The influence of grinding procedures was discussed in another study, which found that the availability of some analytes was significantly influenced by the degree of grinding in some soils.[237]

Significant interest still exists in microwave extraction methods.[238–241] In one investigation, the microwave extraction of cadmium in a soil reference material gave results comparable to those found after using conventional extraction procedures.[238]

In another study, microwave versus conventional dissolution was compared for soils, sludges, sediments, and oils.[239] By microwave digestion of dust samples with a nitric acid/hydrofluoric acid mixture, over 90% of Pb and Cd were recovered within 30 min.[240] Microwave digestion procedures for the analysis of metal-contaminated soils were also reviewed.[241]

Other extraction procedures for metals in soils and sediments were studied. For the determination of lead in roadside soil, HCl, HNO_3, $HClO_4$, aqua regia and EDTA were used for the digestion.[242] Among them the digestion with a mixture of aqua regia and EDTA yielded the highest level of lead content. However, 90% extraction was possible when EDTA was used as the extraction medium. The EDTA extraction procedure was evaluated in a collaborative study between six laboratories.[243] All laboratories produced some extreme outlying results, but most results were in good agreement once the outliers were removed. Acceptable accuracy and precision were obtained for metals in soil using an ultrasonic bath digestion procedure.[244] An interlaboratory comparison study was reported involving 160 accredited hazardous materials laboratories.[245] In this study, each laboratory performed a mineral acid digestion on five soils spiked with As, Cd, Mo, Se, and Tl.

5.3 Techniques Used for Soil and Sediment Analysis

Square-wave CSV was used for the determination of selenium in soils and sediments.[246] Speciation of As(III) and As(V) in soils was accomplished under different pH conditions by CSV.[247] Other developments in the determination of heavy metals in soil and sediments were reported.[248,249] The lead content of roadside soil in Ankara was determined using ASV.[242] The deposition potential was -0.800 V in the presence of EDTA and $HClO_4$ at pH 2.0 and the deposition time was 5 min. After a rest period of 45 s, a potential sweep of 60 mV s^{-1} was applied in a positive direction and the current was recorded. Under these conditions, 10^{-7} M lead could be determined with better than 95% accuracy. As expected the lead content of the soil increased with increasing traffic volume, changing from 193 to 710 ppm. A convenient and accurate analytical procedure has been developed for the simultaneous determination of Cd, Cu, Pb, and Zn in soils.[250] This method is based on DPASV measurement, at an HMDE, of the analytes resulting from the digested soil. Some samples were analyzed by DPASV and AAS to ascertain the applicability of the developed procedure. Good agreement was found between the results obtained with both methods. Selenium has been analyzed in soils and plants by DPCSV at the HMDE.[251] Oxygen-flask digestion of the sample was followed by treatment with HCl to reduce Se(VI) to Se(IV). The voltammogram was then recorded and Se concentration was determined by means of its second

stripping peak. Results obtained by DPCSV showed reasonable agreement with those of fluorimetric analysis for Se content above $0.1\,\mu g\,g^{-1}$, and the detection limit of $5\,ng\,g^{-1}$ was similar for both methods. A simple and sensitive adsorptive catalytic stripping (voltammetric and (chrono)potentiometric) procedure for determining trace amounts of chromium in soil samples was developed by Wang et al.[252] A preconcentration time of 1 min using a preconcentration potential of $-0.82\,V$ (versus Ag/AgCl) resulted in a detection limit of $1\,ng\,L^{-1}$. The identical stripping response for Cr(III) and Cr(VI) solutions makes the method applicable to the measurement of the total Cr. Groundwater and soil samples from contaminated nuclear energy sites were also analyzed.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectrometry
ADSV	Adsorptive Stripping Voltammetry
ASV	Anodic Stripping Voltammetry
CSV	Cathodic Stripping Voltammetry
DC	Direct Current
DME	Dropping Mercury Electrode
DMG	Dimethylglyoxime
DP	Differential Pulse
DPASV	Differential Pulse Anodic Stripping Voltammetry
DPCASV	Differential Pulse Catalytic Adsorptive Stripping Voltammetry
DPCSV	Differential Pulse Cathodic Stripping Voltammetry
DPP	Differential Pulse Polarography
DTC	Dithiocarbamate
DTPA	Diethylenetriaminepentaacetic Acid
EC	Electrochemical
EDTA	Ethylenediamine Tetraacetic Acid
FIA	Flow Injection Analysis
GCE	Glassy Carbon Electrode
HMDE	Hanging Mercury Drop Electrode
HPLC	High-performance Liquid Chromatography
ICPMS	Inductively Coupled Plasma Mass Spectrometry
MA	Mandelic Acid
MFE	Mercury Film Electrode
NAA	Neutron Activation Analysis
PIXE	Particle-induced X-ray Emission
PSA	Potentiometric Stripping Analysis
RRDE	Rotating Ring Disc Electrode
TGA	Thioglycolic Acid

Ion chromatography (IC) is a subset of liquid chromatography applied to the determination of ionic solutes, such as inorganic anions, cations, transition metals, and low-molecular-weight organic acids and bases. Although these solutes can be analyzed using a number of separation and detection modes, ion-exchange is the primary separation mode and suppressed conductivity is the primary method of detection in IC. Method detection limits (MDLs) for inorganic anions and cations are typically in the low parts per billion range and recoveries obtained for ions in spiked water samples are generally in the order of 80–110%. The linear calibration range extends from low parts per billion to mid parts per million concentrations for most applications. IC is well established as regulatory method for the analysis of inorganic anions in environmental samples as there are few alternative methods which can determine multiple anions in a single analysis. However, there are relatively few regulatory methods for cation analysis which use IC. Methods for cation analysis tend to be based upon spectroscopic techniques, although IC offers the advantage of providing information on metal speciation. The main interferences in IC are generally other ions which elute within the timeframe of the ion(s) of interest, and the determination of trace ions in the presence of high levels of other ionic species remains the most difficult of analyses with this technique.

1 INTRODUCTION

1.1 Historical Perspective

The origins of modern IC were laid down by Hamish Small et al. at Dow Chemical in 1975, when they first described a novel ion-exchange chromatographic method for the separation and conductimetric detection of ionic species.[1] They employed a low-capacity, ion-exchange stationary phase for the separation of analyte ions, in conjunction with a second ion-exchange column and conductivity detector, which allowed for continuous monitoring of the eluted ions. The second column was called a 'stripper' column (later termed a 'suppressor') and served to reduce the background conductance of the eluent and enhance the detectability of the eluted ions. In the case of anion analysis, this was achieved by exchanging hydronium ions from the cation-exchange suppressor for cocations (e.g. sodium) in the eluent, prior to the measurement of conductance. This results in conversion of the eluent anion to its less-conductive weak-acid form, while enhancing the conductance of the analyte ion pair as a result of replacing the less-conductive cocation with the more conductive hydronium ion. The reverse situation can be described for cation analysis, where the suppressor is an anion-exchange column and the eluent is converted to its less-conductive weak-base form. The term 'IC' was subsequently introduced when this technology was licensed to the Dionex® Corporation for commercial development.

The introduction of IC provided a foundation for renewed interest in the determination of ionic solutes and prompted much investigation into the use of alternative separation and detection approaches for the liquid chromatographic analysis of inorganic compounds. In 1979, Fritz et al. showed that a suppressor was not essential to sensitive conductivity detection, provided that appropriate low-capacity stationary phases and low-conductance eluents were used.[2,3] In addition, the separation of inorganic ions using traditional C_{18} reversed-phase columns was also being explored at about the same time.[4] Since that time, a considerable variety of separation and detection methods have been

employed for the determination of ionic species, as discussed in the article **Ion Chromatography**. This, in turn, has significantly expanded the range of solutes and applications to which IC is now applied.

1.2 Definition and Scope

This diversity has led to the point where IC is typically defined by the range of solutes to which it is applied, rather than any specific combination of separation and detection modes.[5] IC can therefore be considered to encompass liquid chromatographic techniques which can be used for the determination of the following ionic solutes: inorganic anions; inorganic cations including alkali metal, alkaline earth, transition metal, and rare earth ions; low-molecular-weight (water soluble) carboxylic acids plus organic phosphonic and sulfonic acids, including detergents; carbohydrates; low-molecular-weight organic bases; and ionic metal complexes.[5–8] Ion-exchange remains the primary separation mode used in IC today, although other approaches used for the separation of inorganic species include ion interaction, ion exclusion, and chelation chromatography, in addition to reversed-phase separations of metal complexes. Advances in suppressor technology have improved the sensitivity and ease of use of suppressed conductivity detection, although nonsuppressed conductivity and indirect (or vacancy) detection methods are still employed as alternatives for universal detection. Direct detection methods have proven to be highly selective for ultraviolet (UV)-absorbing or electroactive species, whereas postcolumn derivatization followed by UV/VIS (ultraviolet/visible) absorption or fluorescence is an important detection approach for transition metals, lanthanides, and actinides. Additionally, the use of more advanced detection techniques for IC, such as mass spectrometry (MS) and inductively coupled plasma mass spectrometry (ICPMS), continue to be explored.[5]

The growth of IC was very rapid because it provided a reliable and accurate method for the simultaneous determination of many common inorganic ions. In the early stages of its development, IC was viewed as a tool for the determination of simple inorganic species, particularly in environmental samples. The vast majority of the early applications of IC were for the analysis of inorganic anions and cations in environmental samples, such as air-filter extracts, soil extracts, drinking water, and natural-water samples.[9,10] As the range of solutes that could be determined by IC continued to expand, so did the application areas in which the technique was applied. In addition to environmental applications, IC is now routinely used for the analysis of ionic compounds in diverse areas. These include the chemical and petrochemical industries, semiconductor and high-purity water applications, food and beverage applications, the clinical and pharmaceutical industries, and mining and metallurgical applications.

IC can now be considered a well-established, mature technique for the analysis of ionic species and many organizations, such as ASTM (American Society for Testing and Materials), AOAC (Association of Official Analytical Chemists), and USEPA (United States Environmental Protection Agency), have standard or regulatory methods of analysis based upon IC. Despite the diverse range of solutes and sample types currently analyzed by IC, environmental analysis continues to be the largest application area in terms of new instrument sales and the total number of samples analyzed. In terms of the solutes analyzed in environmental applications of IC, inorganic anions are by far the most important. The primary reason for this is the lack of alternative methods for anion analysis, which is not the case for cations, where many other instrumental techniques are available. Consequently, the simultaneous analysis of the common inorganic anions in drinking water and wastewater remains the most important routine application of IC.

2 ALTERNATIVE ANALYTICAL TECHNIQUES

IC is a well-established regulatory technique for the analysis of inorganic anions in environmental samples. Acceptance of IC for the analysis of anionic solutes was very rapid, primarily due to the lack of alternative methods that could determine multiple anions in a single analysis. A variety of methods have been employed for the analysis of inorganic anions: traditional spectroscopic techniques such as colorimetry; wet chemical methods such as gravimetric analysis, turbidimetry, and titrimetry; and electrochemical techniques such the use of an ion-selective electrode (ISE) and amperometric titrations.[11] Many of these methods suffer from interferences and limited sensitivity, they can be labor intensive and are often difficult to automate. The use of flow injection analysis (FIA) enables the automation of certain colorimetric and ISE methods of analysis, although still only for one analyte at a time. Multiple analytes can be determined by adding additional channels to an FIA system; however, this adds complexity and cost to the instrument.

During the early development of IC, many comparisons between wet chemistry methods and IC were performed in order to validate the latter technique. For instance, in a 1984 comparison, IC was found to be equivalent to conventional wet chemistry methods for the determination of common anions (such as chloride, nitrate, and sulfate) in

Table 1 Conventional methods for the analysis of inorganic anions in drinking water[12]

Analyte	Conventional analytical method	Method
Fluoride	ISE	USEPA 340.2
Chloride	Potentiometric titration	[b]APHA 407C
Nitrite	Automated (FIA) sulfanamide[a]	USEPA 354
Nitrate	Automated (FIA) cadmium reduction[a]	USEPA 365.1
Phosphate	Automated (FIA) ascorbic acid[a]	USEPA 353.2
Sulfate	Turbidimetric	USEPA 375.1

[a] FIA methods use spectrophotometry for quantification after appropriate color formation.
[b] American Public Health Association.

drinking-water samples.[12] Table 1 details the approved conventional methods used (at the time) for the analysis of the inorganic anions commonly found in drinking water. Considering that these six individual test procedures could be replaced by one 30 min chromatographic separation, it is not surprising that IC quickly became accepted by regulatory bodies worldwide for the analysis of anions in drinking water.

However, the situation regarding the analysis of cations in environmental samples is quite different to the case for anions. Many rapid and sensitive spectroscopic methods (such as AAS (atomic absorption spectroscopy), ICPAES (inductively coupled plasma atomic emission spectroscopy), and ICPMS) and electrochemical methods (such as polarography and anodic stripping voltammetry) are available for cation analysis. Many of these are multielement techniques and therefore duplicate one of the major attractions of chromatographic methods. Regulatory methods for cation (metal) analysis in environmental samples tend to be based primarily upon AAS and ICP (inductively coupled plasma) instrumentation.[11] However, IC does offer an advantage over spectroscopic techniques for cation analysis in the area of metal speciation. For instance, as IC is a separation-based technique, it can distinguish different metal oxidation states, such Cr(III) and Cr(VI) and also Fe(II) and Fe(III).[13,14] In addition, IC has also been used to determine stable metal complexes, such as metallocyanides and organic arsenic species.[5] Nevertheless, there are only a limited number of environmental regulatory methods for cations based upon IC methodology.

3 SAMPLE HANDLING AND PREPARATION

The primary concerns when collecting environmental samples for analysis using any measurement technique is that the sample collected is representative of the total sample matrix, and that no contamination occurs during the sampling process.[5] Also, appropriate storage and preservation of the sample is required, in order that the final sample analysis is representative of the analyte concentrations present when the sample was originally taken from the field. Appropriate procedures for the collection of representative samples are discussed in detail in the article **Sampling Considerations for Biomonitoring**; however, sample handling and preparation techniques specific to IC analysis are discussed below.

3.1 Sample Storage and Preservation

Water samples collected for analysis by IC ideally should be collected in plastic containers, such as polystyrene or polypropylene bottles, as glass bottles can contribute ionic contamination when performing trace analysis.[15] The bottles should be thoroughly rinsed with reagent-grade

Table 2 Sample preservation and holding times for anions and cations commonly determined by IC[11,16–19]

Analyte	Preservation	Holding time (days)
Acetate	Cool to 4 °C	2
Bromate[a]	Add 50 mg L^{-1} EDA[b]	28
Bromide	None required	28
Chlorate[a]	Add 50 mg L^{-1} EDA	28
Chloride	None required	28
Chlorite[a]	Add 50 mg L^{-1} EDA, cool to 4 °C	14
Chromate	Adjust pH to 9–9.5 with eluent[c]	1
Cyanide	Adjust pH to >12 with NaOH, cool to 4 °C	14
Fluoride	None required	28
Formate	Cool to 4 °C	2
Nitrate[d]	Cool to 4 °C	2
Nitrite[d]	Cool to 4 °C	2
o-Phosphate	Cool to 4 °C	2
Sulfate	None required	28
Ammonium	Filtration, cool to 4 °C	7
Calcium	Filtration	42
Magnesium	Filtration	42
Potassium	Filtration	42
Sodium	Filtration	42
Metals, e.g. Co, Ni, Zn	Acidify to pH < 2 with nitric acid, i.e. 1.5 mL conc. HNO_3 per liter sample	6 months

[a] Samples collected for oxyhalide analysis should be immediately sparged with an inert gas (e.g. nitrogen, argon, or helium) for 5 min to remove active gases such as chlorine dioxide or ozone. Samples for chlorite should be stored in amber containers.
[b] EDA = ethylenediamine.
[c] Eluent = 250 mM ammonium sulfate and 100 mM ammonium hydroxide.
[d] Holding times can be increased by adjusting to pH 12 with sodium hydroxide.

water before use. Sample preservation requirements and holding times for anions and cations typically determined by IC are listed in Table 2.

3.2 Sample Dissolution

The majority of the water samples collected for IC analysis require little or no sample pretreatment. Drinking-water samples, for instance, typically require no pretreatment other than filtration through a 0.45 μm filter to remove particulates. Higher ionic strength water samples, e.g. wastewater, often only require dilution (and filtration) to bring the analytes of interest into the working range of the method. In fact, this so-called dilute-and-shoot approach to sample preparation is one of the advantages of IC when it comes to the practical application of this technique.[20] However, solid samples, such as soils and sludge, are not directly amenable to IC analysis and require additional sample pretreatment.

3.2.1 Aqueous Extraction

The high solubility of ionic species in water means that such solutes can often be removed from solid samples prior to IC analysis simply by aqueous extraction of the finely divided sample. Generally, a weighed amount of the sample is mixed with a known volume of water, or other extracting solution, and homogenized using a blender or ultrasonic probe; alternatively, it is mixed with a magnetic stirrer or rotation flask.[17,21] The choice of extracting solution is dependent on both the sample matrix and the nature of the solute ions.[5] Water is preferred, in order to avoid introducing extraneous peaks into the final chromatogram. However, the following have all been used to extract ionic species from solid samples prior to IC analysis:[5] water combined with a miscible solvent such as methanol; solutions of dilute acid or base; dilute salt solutions, such as potassium chloride or phosphate buffers; or even the eluent solution used for the IC separation. Recoveries from the aqueous extraction of solid samples for low parts per million spikes of leachable solutes, such as fluoride, chloride, bromide, and nitrate, are typically of the order of 82–101%.[22]

3.2.2 Acid Digestion

Many solid samples, such as shale or rocks, are not amenable to simple aqueous extraction and it is necessary to digest the sample to obtain quantitative recoveries of ionic species. This is traditionally performed using concentrated acids (e.g. nitric acid) or their mixtures (e.g. nitric/hydrochloric acids) and is widely used in the preparation of environmental samples prior to analysis using spectroscopic techniques, such as AAS or ICPAES.[11,23] However, acid digestion is often inappropriate for IC because the excess of the acid coanion can lead to the appearance of a large, interfering peak in the final chromatogram and can also cause column overloading.[5] Hence, this approach is typically not employed for anion analysis, unless further sample pretreatment is being used. One important example of this approach is the determination of total cyanide by IC. Cyanide is strongly complexed to certain metals, e.g. iron, and strong acid digestion in the presence of a magnesium chloride catalyst is required to liberate free cyanide. The resulting hydrocyanic acid can be removed from the digestion matrix by reflux distillation and absorbed into a sodium hydroxide solution which can be analyzed for cyanide using IC with amperometric detection.[24] The same approach can also be used for sulfide and fluoride in solid samples.

In general, acid digestion is better suited to preparing samples which are to be analyzed for cations using IC. For instance, total nitrogen (as the ammonium ion) has been determined in environmental samples using IC by direct analysis of the Kjeldahl digest matrix.[25] In addition, transition metals and rare earth elements are frequently analyzed using IC with postcolumn reaction detection after acid digestion of the samples.[5]

3.2.3 Alkali Fusion

Fusion techniques can be an attractive alternative to acid digestion for the preparation of samples of geological materials. A sample is mixed with an alkaline flux and heated at high temperatures (800–1100 °C) until the flux becomes molten. The melt is then cooled and dissolved in a suitable digestion solution prior to analysis by IC. Typical flux materials include sodium peroxide, sodium carbonate, lithium tetraborate, and sodium hydroxide.[26] Care must again be taken to ensure that the final digest solution is compatible with the IC separation. This approach has been used for the determination of fluoride and chloride in geological materials after fusion with sodium carbonate and subsequent injection into an IC device using a carbonate/bicarbonate eluent.[5] Occasionally, this approach is the only means available for obtaining complex samples in solution. For instance, alkali fusion followed by acid digestion proved to be necessary for the complete dissolution of mineral sands when analyzing thorium and uranium by IC with postcolumn reaction detection.[26]

3.2.4 Combustion Methods

Sample combustion is another approach which is commonly used to prepare solid matrices for analysis by IC. This involves total combustion of the sample in oxygen, which converts nonmetallic elements to volatile gaseous

compounds. These gases can be collected into a suitable absorbing solution which can then be analyzed using IC. Combustion methods have been used for the determination of halides and total sulfur, nitrogen, and phosphorus in samples such as plant materials, silicate rocks, coal, and oil shales.[17] The Schoeniger flask is the simplest apparatus for sample combustion. However, the oxygen pressure is limited to atmospheric pressure, which limits the sample size and ultimately the sensitivity of the analysis. Larger samples can be accommodated in a Parr bomb where oxygen pressures as high as 40 atm are used to facilitate sample combustion.[5] The absorbing solution used for halides, which are converted to their corresponding acid gas (e.g. HCl) during combustion is typically dilute sodium hydroxide. A reducing agent, such as hydrazine sulfate, may be added to prevent the formation of oxyanions for bromide and iodide.[27] Alternatively, sulfur and phosphorus are typically quantitated as sulfate and phosphate, respectively, hence the absorbing solution typically contains an oxidizing agent, such as hydrogen peroxide.[28]

3.3 Sample Cleanup

Once a solution has been obtained it is typically necessary to perform some degree of sample pretreatment or cleanup prior to injection into the IC device. This pretreatment may be as simple as filtration, or may be a complicated time-consuming matrix-elimination step. The typical intent of sample cleanup is to achieve one or more of the following goals: (1) removal of particulates which could cause blockages or damage to the instrument; (2) reduce the overall sample loading on the column; (3) concentration or dilution of the target analytes; and (4) removal of matrix interferences.[5]

3.3.1 Filtration

As is the case with all liquid chromatographic methods, samples analyzed by IC should be free of particulates to avoid blockages or damage to connecting tubing, column end frits, and other hardware components. Samples are typically filtered through a 0.45 μm (or less) membrane-based filter. Disposable syringe filters are commercially available and their use greatly simplifies sample filtration. Also, certain types of autoinjectors will automatically filter the sample before injection into the IC instrument. However, the possibility of sample contamination from these devices can be a concern, particularly when performing trace analysis. Rinsing filters with 20 mL of deionized water prior to filtration of the sample has been shown to remove most inorganic contaminants.[29]

3.3.2 Matrix Elimination

Complex aqueous samples, such as wastewaters and solid leachates, often require further chemical modification (cleanup) of the sample in order to eliminate matrix interferences. Solid-phase extraction (SPE) cartridges represent the most convenient means of removing interferences prior to ion chromatographic analysis.[30] These commercially available disposable cartridges enable rapid sample pretreatment and require only small volumes of sample. SPE cartridges are available with many different chromatographic packing materials; including silica, alumina, C_{18}, anion-exchange resins (OH^- form), cation-exchange resins (H^+, Ag^+, Ba^+ forms), neutral polymer, amino, and activated carbon.[5] These cartridges can be employed in a number of different modes of operation with IC analyses, as discussed below.

- Hydrophobic SPE cartridges, e.g. C_{18} and neutral polymers, can be used to remove neutral organic compounds, while allowing inorganic ions to pass through unretained. Hydrophobic organic compounds do not typically interfere during an IC separation; however, they can be strongly retained on the stationary phase material which can lead to decreased column lifetimes. This approach is typically required when using IC for the analysis of ions in food and biological matrices, or wastewaters and soil leachates containing high levels of organics, e.g. humic acids.[17,21]
- Cation- and anion-exchange SPE cartridges in the H^+ and OH^- forms, respectively, can be used to adjust sample pH and reduce total ionic strength without adding a potentially interfering coanion (for acids) or cocation (for bases) to the sample.[30]
- Cation-exchange SPE cartridges in the H^+ form can be used to remove carbonate and cationic species, such as $iron^{III}$ and aluminum, which may precipitate under alkaline eluent conditions.[17] Cation-exchange cartridges in the Ag^+ and Ba^+ forms can be used to selectively remove halides and sulfate from samples by precipitating insoluble silver halides or barium sulfate, respectively.[30] The Ag^+ form cartridges are widely used to selectively remove chloride from environmental waters to allow trace analysis of anions, such as bromate in ozonated waters, which would otherwise be masked by the excess chloride.[31]

Recently, SPE disks have become available as an alternative to the cartridge configuration. These disks are available with many of the same packings as the cartridges, although their geometry allows the use of higher sample loading flow rates.[32] The use of dialysis across membranes offers another means of reducing sample interferences, and this approach has been used

to reduce sample acidity,[33] basicity,[34] and also chloride in brine samples prior to IC analysis.[35]

3.3.3 On-line Matrix Elimination

Many of the sample preparation techniques described above can also be performed using on-line instrumentation. This approach offers the benefits of greater precision and the process can often be automated, although the instrumentation is usually more complex. The most common application of on-line matrix elimination in IC is sample preconcentration. A measured volume of sample is first passed through an ion-exchange concentrator column and the solute ions are retained on this column, while the bulk sample solution (i.e. water) passes through to waste. The concentrator column is then switched to be in line with the eluent, which carries the solute ions through to the analytical column to be separated and detected in the usual manner.[5] This approach is frequently used for the determination of trace ions in high-purity waters, e.g. steam and boiler feed water for power station generators.[36]

Sample preconcentration can also be successfully applied to high-ionic-strength samples, particularly if the solutes of interest are strongly retained on the concentrator column. The strongly retained solutes can be trapped on the concentrator column while weakly retained solutes and water pass through to waste. This approach, which effectively combines sample preconcentration with matrix elimination, has been used for the determination of anions in aqueous vegetation extracts and low parts per billion levels of precious metal cyanide complexes in gold tailings solutions.[37,38] A variation on using ion-exchange columns to selectively concentrate ionic solutes prior to IC analysis is the use of chelating resins. These materials can be used to selectively complex transition metal and rare earth elements in the presence of high levels of alkali and alkaline earth metals. This approach has been employed for the on-line cleanup and concentration of low parts per billion levels of transition metals and lanthanides in complex geological matrices and seawater prior to analysis by IC or ICPMS.[39]

Automated matrix elimination can also be performed using heart-cut techniques. This involves loading the sample onto a short column, then carefully switching only the fraction of eluent containing the solute(s) of interest towards the separator column. This approach, which typically performs best when the sample matrix has a consistent composition, has been used for the determination of trace anions in samples containing high levels of chloride.[20]

4 REGULATORY METHODS OF ANALYSIS

IC has been approved by many standard or regulatory organizations in numerous countries for the analysis of

Table 3 Regulatory IC methods approved in the USA for environmental water and waste analysis

Method	Analytes	Matrices[a]
EPA Method 300.0 (A)	F, Cl, NO_2, Br, NO_3, PO_4, SO_4	rw, dw, sw, ww, gw, se
EPA Method 300.0 (B)	BrO_3, ClO_3, ClO_2	Raw water, dw
EPA Method 300.1 (A)	F, Cl, NO_2, Br, NO_3, PO_4, SO_4	rw, dw, sw, gw
EPA Method 300.1 (B)	BrO_3, Br, ClO_3, ClO_2	rw, dw, sw, gw
EPA SW-846 9056	F, Cl, Br, NO_3, PO_4, SO_4	Combustion extracts, all waters
ASTM D 4327-97	F, Cl, NO_2, Br, NO_3, PO_4, SO_4	dw, ww
Standard Methods[11] 4110	Cl, NO_2, Br, NO_3, PO_4, SO_4	rw, dw, ww
EPA Method 300.6	Cl, NO_3, PO_4, SO_4	Wet deposition, rain, snow, dew, sleet, hail
ASTM D 5085-90	Cl, NO_3, SO_4	Wet deposition, rain, snow, sleet, hail
EPA Method B-1011	NO_2, NO_3	rw, dw
EPA SW-846 9058[b]	ClO_4	rw, dw, gw
ASTM D 2036-97	CN	dw, sw, ww
ASTM D19.05.03.22[b]	Total $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$	dw, gw, ww
EPA Method 218.6	Hexavalent chromium (CrO_4^{2-})	dw, gw, ww
EPA SW-846 7199	Hexavalent chromium (CrO_4^{2-})	dw, gw, ww
ASTM D 5257-93	Hexavalent chromium (CrO_4^{2-})	dw, sw, ww
ASTM D19.05.03.23[b]	Na, NH_4, K, Mg, Ca	rw, sw, gw, ww
EPA Method 300.7	Na, NH_4, K, Mg, Ca	Wet deposition, rain, snow, dew, sleet, hail
EPA Method 200.10[c]	Cd, Co, Cu, Pb, Ni, U, V	Brines, seawater, mw, ew
EPA Method 200.13[c]	Cd, Co, Cu, Pb, Ni	Brines, seawater, mw, ew

[a] Matrices: rw = reagent water; dw = drinking water; sw = surface water; ww = wastewater (mixed domestic and industrial); gw = ground water; se = solid extracts; mw = marine water; ew = estuarine water.
[b] Proposed method, in draft form only.
[c] IC used for cleanup and concentration prior to spectroscopic analysis.

both anions and cations in environmental samples. The majority of the approved methods are for the analysis of anionic solutes; however, some approved methods exist for cations. Although a complete listing of approved IC methods worldwide is beyond the scope of this article, a list of the most important regulatory IC methods used for environmental water and waste analysis in the USA is given in Table 3.[40]

Many different regulatory agencies promulgate what are essentially similar methods, as Table 3 illustrates. For instance, ASTM D 4327-97 uses the same methodology as USEPA Method 300.0(A); however, each agency has a unique method format and writing style. Also, differences exist between the methods in the area of quality control (QC). Thus QC is mandated in most USEPA methods whereas it is currently optional in ASTM methods. Different regulatory agencies exist even within the USEPA; hence Method 300.0 is applicable to the analysis of inorganic anions in drinking water and wastewater under direction of the Office of Groundwater and Drinking Water, whereas Method 9056 is applicable to the analysis of inorganic anions in all water types and combustion bomb extracts under direction of the Office of Solid Waste and Emergency Response.

In addition to the methods shown in Table 3 which use IC for environmental water and waste analysis, a considerable number of IC methods are employed for air analysis. Regulatory bodies, such as the National Institute of Occupational Safety and Health (NIOSH) and the Occupational Safety and Health Administration (OSHA), specify IC for the analysis of compounds in air and workplace atmospheres that form ionic species in solution (e.g. formic acid, sulfur dioxide, nitrous oxides, ammonia, and hexavalent chromium).

Although Table 3 details only methods approved in the USA, many industrial countries around the world have similar health and environmental standards; consequently, a considerable number of regulatory IC methods exist worldwide. For instance, German Methods DIN 38 405 (D 20) and DIN ISO (International Organization for Standardization) 10 304-1 are similar to USEPA Method 300.0, whereas DIN 38 405 (D 22) is applicable to the determination of chromate, iodide, sulfite, thiocyanate, and thiosulfate in water matrices. French Method AFNOR T90-042 is again similar to EPA Method 300.0, as is the Italian method UNICHIM 926 (1991). Several IC methods are approved in Japan for the analysis of anions in matrices, such as industrial waters (K0101), industrial wastewater (K0102), mine water, and wastewater (M0202).[41] Japan also has a method detailing general rules for IC analysis (K0127), whereas Standards Australia has a recommended practice for chemical analysis by IC (AS 3741-1990).[42]

5 WATER AND WASTEWATER ANALYSIS

5.1 Drinking Water and Wastewater

Water quality in the USA is legislated through the Safe Drinking Water Act (SDWA) and the Clean Water Act (CWA). The SDWA ensures the integrity and safety of US drinking water, whereas the goal of the CWA is to reduce the discharge of pollutants into US waters. The majority of the regulatory methods of analysis that use IC are validated for both drinking water and wastewater, hence these matrices will be considered together.

5.1.1 Common Inorganic Anions

The US National Primary Drinking Water Standards specifies a maximum contaminant level (MCL) for a number of common inorganic anions, including fluoride, nitrite, and nitrate. The MCLs are specified to minimize potential health effects arising from the ingestion of these anions in drinking water. For instance, high levels of fluoride causes skeletal and dental fluorosis, whereas nitrite and nitrate can cause methemoglobulinemia, which can be fatal to infants.[21] Consequently, the analysis of these anions in drinking waters is mandated, as are the analytical methods used for their quantification. Other common anions, such as chloride and sulfate, are considered secondary contaminants. The Secondary Drinking Water Standards are guidelines regarding taste, odor, color and certain aesthetic effects that are not federally enforced. However, they are recommended to all states as reasonable goals and many of the states adopt their own enforceable regulations governing these contaminants.[43]

IC has been approved for compliance monitoring of these common inorganic anions in drinking water in the USA since the mid-1980s, as described in EPA Method 300.0. This same method received interim approval for the analysis of inorganic anions in wastewater under the National Pollution Discharge Elimination System (NPDES) permits program in 1992. Method 300.0 specifies the use of a Dionex® AS4A anion-exchange column with an eluent of 1.7 mM sodium bicarbonate/1.8 mM sodium carbonate for the separation of common anions. An optional column may be substituted provided comparable resolution of peaks is obtained and that the QC requirements of the method can be met.[22] Conductivity detection is used for quantification after suppression of the eluent conductance with an anion micro-membrane suppressor (AMMS) or similar device.

Figure 1 shows a chromatogram of a standard containing low parts per million levels of common anions obtained using the conditions described in Method 300.0. All the anions are well-resolved within a total run time of less than 8 min. The application range and MDLs that can be achieved for each of the anions using

Figure 1 Separation of low parts per million anion standard using EPA Method 300.0. Conditions: column, Dionex® IonPac® AS4A-SC; eluent, 1.8 mM sodium carbonate/1.7 mM sodium bicarbonate; flow rate, 2.0 mL min^{-1}; detection, suppressed conductivity with an anion self-regenerating suppressor (ASRS) operated at 50 mA in recycle mode; injection volume, 25 µL; solutes, 1 = fluoride (2 mg L^{-1}), 2 = chloride (3 mg L^{-1}), 3 = nitrite (5 mg L^{-1}), 4 = bromide (10 mg L^{-1}), 5 = nitrate (10 mg L^{-1}), 6 = phosphate (15 mg L^{-1}), 7 = sulfate (15 mg L^{-1}).

Table 4 USEPA Method 300.0 application ranges and detection limits (DLs)[22]

Analyte	Application range (mg L^{-1})	MDL (mg L^{-1})
Fluoride	0.26–8.49	0.01
Chloride	0.78–26.0	0.02
Nitrite-N	0.36–12.0	0.004
Bromide	0.63–21.0	0.01
Nitrate-N	0.42–14.0	0.002
Orthophosphate-P	0.69–23.1	0.003
Sulfate	2.85–95.0	0.02

Method 300.0 are shown in Table 4. Similar methods, such as ASTM D 4327-97 and Standard Methods 4110, provide comparable performance. Advances in column and suppressor technology continues to improve the methodology for determination of these common anions. The IonPac® AS14 column provides complete resolution of fluoride and acetate and also improved resolution of fluoride from the void peak compared to the AS4A column. Figure 2 shows a chromatogram of a typical drinking-water sample obtained using an AS14 column with a 3.5 mM bicarbonate/1.0 mM carbonate eluent and suppressed conductivity detection.

EPA Method 300.0 is also validated for wastewater analysis, although such samples often require sample pretreatment before injection into the ion chromatograph. Dilution into the application range followed by filtration is often required, whereas pretreatment with SPE cartridges to remove hydrophobic organic material

Figure 2 Determination of inorganic anions in drinking water. Conditions as for Figure 1, except: column, Dionex® IonPac® AS14; eluent, 3.5 mM sodium carbonate/1.0 mM sodium bicarbonate; injection volume, 50 µL; solutes, 1 = fluoride (0.03 mg L^{-1}), 2 = chloride (10.1 mg L^{-1}), 3 = nitrate (3.7 mg L^{-1}), 4 = phosphate (0.04 mg L^{-1}), 5 = sulfate (12.2 mg L^{-1}).

Figure 3 Determination of anions in domestic wastewater. Conditions as for Figure 1, except: injection volume, 50 µL; sample preparation, SPE cleanup with a Waters C_{18} Sep-Pak®; solutes, 1 = injection peak, 2 = acetate (4.2 mg L^{-1}), 3 = bicarbonate (not quantitated), 4 = chloride (49 mg L^{-1}), 5 = bromide (0.04 mg L^{-1}), 6 = nitrate (0.03 mg L^{-1}), 7 = phosphate (28 mg L^{-1}), 8 = sulfate (35 mg L^{-1}).

is recommended to prolong column lifetimes. Figure 3 shows a chromatogram of a typical domestic wastewater sample obtained using an AS4A column with a carbonate/bicarbonate eluent and suppressed conductivity detection. The performance of environmental methods, such as EPA Method 300.0, is typically validated through single- and multioperator precision and bias studies on spiked samples. Table 5 shows single-operator precision and bias data obtained using Method 300.0 for common anions spiked into reagent water, drinking water, and mixed domestic and industrial wastewaters. Acceptable precision and bias data were obtained for the determination of common anions in all three matrix types when using IC.

Table 5 USEPA Method 300.0 single-operator precision and bias[22]

Analyte	Matrices[a]	Added concentration ($mg\,L^{-1}$)	Mean[b] recovery (%)	Standard deviation ($mg\,L^{-1}$)
Fluoride	rw	2.0	91	0.05
	dw	1.0	92	0.06
	ww	1.0	87	0.07
Chloride	rw	20.0	96	0.35

	ww	40.0	102	6.4

[a] Matrices: rw = reagent water; dw = drinking water; ww = wastewater (mixed domestic and industrial).
[b] Average of seven replicates.

5.1.2 Disinfection By-product Anions

USEPA Method 300.0 was revised in 1993 to include determination of the disinfection by-product (DBP) anions – bromate, chlorite, and chlorate. Bromate is a DBP produced from the ozonation of source water that contains naturally occurring bromide, whereas chlorite and chlorate are produced as a result of using chlorine dioxide as a disinfectant. These DBP anions pose significant health risks, even at low microgram per liter levels. Bromate has been judged as a potential carcinogen and the USEPA has estimated a potential cancer risk equivalent to 1 in 10^4 for a lifetime exposure to drinking water containing bromate at $5\,\mu g\,L^{-1}$.[44]

The occurrence of bromate and other DBPs in US drinking water has recently been documented by the USEPA through the comprehensive collection of data mandated by the information collection rule (ICR). The USEPA has proposed an MCL for bromate of $10\,\mu g\,L^{-1}$ and an MCL for chlorite of $1000\,\mu g\,L^{-1}$ in finished drinking water, which was promulgated in Stage I of the disinfectant and disinfection by-product (D/DBP) rule.[45] USEPA Method 300.0(B) specifies the use of a Dionex® AS9-SC anion-exchange column with a 1.7 mM sodium bicarbonate/1.8 mM sodium carbonate eluent and suppressed conductivity detection for the analysis of bromate, chlorite, and chlorate. However, Method 300.0(B), as originally published, cannot meet the quantitation requirements of the ICR and method modifications are required. These include the use of a weaker borate eluent to improve bromate and chloride resolution and the use of sample pretreatment to minimize chloride interference.[46]

In support of the publication of Stage I of the D/DBP rule, the USEPA recently developed Method 300.1 for the determination of inorganic and DBP anions. Method 300.1 specifies a Dionex® AS9-HC anion exchange column with a 9.0 mM sodium carbonate eluent and suppressed conductivity detection. The AS9-HC differs from the column specified in Method 300.0(B) in that it has higher capacity and improved separation of the key oxyhalide anions from potential interferences. Method 300.1(A) is applicable to common inorganic anions in drinking water, whereas 300.1(B) is applicable to the determination of DBP anions, and bromide, in drinking water. Methods 300.1(A) and (B) use different injection volumes to achieve different MDLs. Method 300.1(A) requires 10 µL whereas 300.1(B) requires 50 µL when using a 2 mm ID (internal diameter) column, or 50 µL and 200 µL injections, respectively, with a 4 mm ID column.[16] The relatively large injection volume is required for 300.1(B) in order to achieve the DLs necessary when analyzing DBP anions.

Figure 4 shows the separation of chlorite, bromate, and chlorate, in addition to the common inorganic anions using an AS9-HC column. The MDLs for 300.1(B) using a 50 µL injection and 2 mm ID column are 0.89, 1.44, 1.44, and $1.31\,\mu g\,L^{-1}$ for chlorite, bromate,

Figure 4 Separation of oxyhalides plus common inorganic anions using EPA Method 300.1. Conditions: column, Dionex® IonPac® AS9-HC (4 mm ID); eluent, 9.0 mM sodium carbonate; flow rate, $1.0\,mL\,min^{-1}$; detection, suppressed conductivity with an ASRS operated at 100 mA in external water mode; injection volume, 25 µL; solutes, 1 = fluoride ($3\,mg\,L^{-1}$), 2 = chlorite ($10\,mg\,L^{-1}$), 3 = bromate ($20\,mg\,L^{-1}$), 4 = chloride ($6\,mg\,L^{-1}$), 5 = nitrite ($15\,mg\,L^{-1}$), 6 = bromide ($25\,mg\,L^{-1}$), 7 = chlorate ($25\,mg\,L^{-1}$), 8 = nitrate ($25\,mg\,L^{-1}$), 9 = phosphate ($40\,mg\,L^{-1}$), 10 = sulfate ($30\,mg\,L^{-1}$).

Figure 5 Determination of low-level oxyhalides and common anions in simulated drinking water. Conditions as for Figure 4, except: injection volume, 200 μL; solutes, 1 = fluoride (1 mg L^{-1}), 2 = chlorite (0.01 g L^{-1}), 3 = bromate (0.005 mg L^{-1}), 4 = chloride (50 mg L^{-1}), 5 = nitrite (0.1 mg L^{-1}), 6 = bromide (0.01 mg L^{-1}), 7 = chlorate (0.01 mg L^{-1}), 8 = nitrate (10 mg L^{-1}), 9 = phosphate (0.1 mg L^{-1}), 10 = sulfate (50 mg L^{-1}).

bromide, and chlorate respectively.[16] Figure 5 shows the chromatogram of a synthetic drinking water sample obtained using an AS9-HC column with a 9.0 mM carbonate eluent and suppressed conductivity detection. Despite using a 200 μL injection, no column overloading occurs and bromate can be determined at 5 μg L^{-1} in the presence of a 10 000-fold excess of chloride.[47] Figure 6 shows the application of Method 300.1(B) to the determination of DBP anions in drinking water from Sunnyvale, California. The water in this municipality is disinfected using hypochlorite, hence chlorate appears in the drinking water matrix, shown in Figure 6(a). The same drinking water spiked with 10 μg L^{-1} each of chlorite, bromate, bromide, and chlorate is shown in Figure 6(b), indicating that the DBP anions are clearly resolved from the common inorganic anions (and bromide) present in drinking water. Table 6 shows single-operator precision and bias data obtained using Method 300.1 for the DBP anions spiked into reagent water, drinking water, and high-ionic-strength drinking water.

5.1.3 Hexavalent Chromium

USEPA Methods 300.0 and 300.1, and equivalent methods in the USA and other countries, represent the most important and widely used applications of IC in environmental analysis. However, a number of other regulatory methods based on IC are applicable to drinking-water and wastewater analysis. Inorganic chromium is a primary drinking-water contaminant with an MCL of 0.1 mg L^{-1}. Hexavalent chromium is the most toxic form of the metal,

Figure 6 Determination of oxyhalides and common anions in Sunnyvale drinking water. Conditions as for Figure 4, except: sample, (a) drinking water and (b) drinking water spiked with 0.01 mg L^{-1} of oxyhalide anions and bromide; solutes, (a) 1 = fluoride (0.05 mg L^{-1}), 4 = chloride (19 mg L^{-1}), 6 = bromide (0.004 mg L^{-1}), 7 = chlorate (0.03 mg L^{-1}), 8 = nitrate (1.7 mg L^{-1}), 9 = phosphate (0.25 mg L^{-1}), 10 = sulfate (30 mg L^{-1}) and (b) 1 = fluoride (0.05 mg L^{-1}), 2 = chlorite (0.008 g L^{-1}), 3 = bromate (0.012 mg L^{-1}), 4 = chloride (19 mg L^{-1}), 6 = bromide (0.013 mg L^{-1}), 7 = chlorate (0.041 mg L^{-1}), 8 = nitrate (1.7 mg L^{-1}), 9 = phosphate (0.25 mg L^{-1}), 10 = sulfate (30 mg L^{-1}).

Table 6 USEPA Method 300.1 single-operator precision and bias[16]

Analyte	Matrices[a]	Added concentration (μg L^{-1})	Mean[b] recovery (%)	Standard deviation (μg L^{-1})
Chlorite	rw	100	96.2	0.95
	O3w	100	84.4	0.46
	hiw	100	102	2.19
Bromate	rw	5.00	101	0.45
	O3w	5.00	80.9	0.61
	hiw	5.00	97.5	0.95
Bromide	rw	20.0	104	0.80
	O3w	20.0	–[c]	3.67
	hiw	20.0	92.5	0.79
Chlorate	rw	100	98.3	0.80
	O3w	100	100	1.20
	hiw	100	86.1	1.47

[a] Matrices: rw = reagent water; O3w = ozonated drinking water; hiw = high-ionic-strength simulated drinking water.
[b] Average of nine replicates.
[c] Not calculated, as added amount was less than the unfortified amount.

in addition to being a suspected carcinogen. Hexavalent chromium can be separated as the chromate anion using a high capacity Dionex® AS7 anion-exchange column, as specified in USEPA Method 218.6.[18] In this case, detection is achieved using a UV/VIS detector after postcolumn reaction with diphenylcarbohydrazide, as this color-forming reagent provides a more sensitive and selective means for determining chromate than suppressed conductivity.

USEPA Method 218.6 and ASTM D 5257-93 are validated for the determination of hexavalent chromium in drinking water, groundwaters and industrial wastewaters. An MDL of $0.3\,\mu g\,L^{-1}$ for Cr(VI) in drinking and wastewater can be achieved using a 250 µL injection. Average recoveries in the order of 98–105% were obtained for $100\,\mu g\,L^{-1}$ Cr(VI) solutions spiked into reagent, drinking, ground, primary sewage waste and electroplating wastewaters.[16] Figure 7 shows a chromatogram of a spiked wastewater sample obtained using the conditions described in USEPA Method 218.6. No interfering peaks are observed when using this very specific detection approach for Cr(VI) analysis.

5.1.4 Cyanide

The highly toxic cyanide anion is a primary drinking-water contaminant which has an MCL of $0.2\,mg\,L^{-1}$. Sources of cyanide contamination in drinking water include effluents from the electroplating, steel, plastics and mining industries, in addition to certain fertilizers.[43]

Figure 7 Determination of chromate in spiked wastewater using EPA Method 218.6. Conditions: column, Dionex® AS7; eluent, 250 mM ammonium sulfate/100 mM ammonium hydroxide; flow rate, $1.5\,mL\,min^{-1}$; detection, UV/VIS at 530 nm after postcolumn reaction with 2 mM diphenylcarbazide/10% methanol/1.0 N sulfuric acid delivered at $0.5\,mL\,min^{-1}$; injection volume, 100 µL; sample, filtered wastewater spiked with $50\,\mu g\,L^{-1}$ chromate.

Cyanide is classified according to its availability in the presence of complexing metals. Total cyanide refers to CN that can be released as hydrocyanic acid (HCN) from both the aqueous and particulate portions of a sample under total reflux distillation conditions and includes both free and complex cyanides. Free cyanide refers to CN that can be released as hydrocyanic acid from the aqueous portion of a sample by direct cyanide determination without reflux distillation. Cyanide amenable to chlorination refers to CN determined after chlorinating a portion of sample, and calculating the difference between total cyanide in the original and chlorinated samples. Weak acid dissociable cyanide refers to CN determined after distillation with a weak acid. This only releases CN bound in weak complexes, i.e. those with low stability constants, such as with Cu or Zn.[24]

In practice, the majority of CN determinations, particularly in wastewater samples, involve measurement of total CN, which is determined after reflux distillation of an alkaline sample in the presence of sulfuric acid and a magnesium chloride catalyst.[24] The released HCN is absorbed into a sodium hydroxide scrubber solution and the cyanide in this solution can be measured colorimetrically, by IC, FIA, titration, or ISE. An IC separation is recommended with electrochemical detection when sulfur, thiocyanate, or other sulfur-containing compounds are present in the sample, as H_2S codistills with HCN and can interfere with the FIA determination when using electrochemical detection.[24]

ASTM D 2036-97 is validated for the determination of total cyanide in drinking, ground, and surface waters, and both domestic and industrial wastes using IC, in addition to other analytical measurement techniques. Cyanide is separated on a Dionex® AS7 anion-exchange column using an eluent of 100 mM sodium hydroxide/500 mM sodium acetate/0.5% (V/V) ethylenediamine. The CN is then detected using an amperometric detector with a silver working electrode operated at −0.05 V.[24] This very sensitive detection approach provides an MDL of $2\,\mu g\,L^{-1}$ when using a 1.0 mL injection volume and can tolerate sulfur concentrations up to 100 times the cyanide level without degradation of method performance. Figure 8 shows a chromatogram of cyanide and sulfide in a spiked wastewater sample obtained using an AS7 column and amperometric detection. The applicable range of this method is from $10\,\mu g\,L^{-1}$ to $10\,mg\,L^{-1}$ cyanide; mean recoveries in the order of 85–98% were obtained for samples spiked with CN over the range $40–1000\,\mu g\,L^{-1}$.

5.1.5 Perchlorate

Ammonium perchlorate is a key ingredient in solid rocket propellants which has recently been found in groundwaters in regions of the USA where aerospace

Figure 8 Determination of sulfide and cyanide in spiked wastewater using ASTM Method D2036-97. Conditions: column, Dionex® IonPac® AS7; eluent, 500 mM sodium acetate/100 mM sodium hydroxide; flow rate, 1.0 mL min^{-1}; detection, amperometry using a silver working electrode operated at −0.05 V versus Ag/AgCl reference; injection volume, 100 µL; sample, filtered spiked wastewater; solutes, 1 = sulfide (25 µg L^{-1}), 2 = cyanide (100 µg L^{-1}).

material, munitions, and fireworks have been developed, tested, or manufactured. Perchlorate has been found in ground and surface waters in California, Nevada, Utah, and West Virgina.[48] Perchlorate poses a human health risk and preliminary data from the USEPA reports that exposure to less than 4–18 µg L^{-1} as providing adequate health protection.[49] Perchlorate is listed on the USEPA contaminant candidate list as a research priority, although it is not currently regulated under the Federal SDWA.[43] Perchlorate contamination of public drinking-water wells is becoming a serious problem in some western States and the California Department of Health Services (CDHS) has adopted an action level for perchlorate in drinking water of 18 µg L^{-1}. To date, perchlorate has been detected in over 100 public drinking-water wells in California, with more than 20 wells being closed due to contamination.[49]

The CDHS developed an IC method based on the use of an hydrophilic IonPac® AS5 column, large loop injection, and suppressed conductivity detection to quantify perchlorate at low microgram per liter levels.[50] However, the use of an IonPac® AS11 column with an eluent of 100 mM hydroxide, 1000 µL injection, and suppressed conductivity detection provides an MDL for perchlorate of 0.3 µg L^{-1} without the need for an organic modifier in the mobile phase.[48] Figure 9 shows a chromatogram of perchlorate standard at 20 µg L^{-1}, whereas Figure 10 shows a drinking water sample spiked

Figure 9 Chromatogram of 20 µg L^{-1} perchlorate standard. Conditions: column, Dionex® IonPac® AS11; eluent, 100 mM sodium hydroxide; flow rate, 1.0 mL min^{-1}; detection, suppressed conductivity with an ASRS-Ultra operated at 300 mA in external water mode; injection volume, 1000 µL; solute, perchlorate.

Figure 10 Analysis of perchlorate in spiked drinking water. Conditions as for Figure 9, except: sample, filtered Sunnyvale, CA, tapwater spiked with 6 µg L^{-1} perchlorate.

with 6.0 µg L^{-1} perchlorate. The applicable range of this method is from 2.0 to 100 µg L^{-1} perchlorate. The method is free of interferences from common anions and quantitative recoveries were obtained for low microgram per liter levels of perchlorate in spiked drinking and groundwater samples.[48]

5.1.6 Inorganic Cations and Ammonia

The preceding discussion shows that a number of regulatory methods based on IC are available for anion analysis; however, that is not case for cation analysis. The majority of the inorganic cations listed as primary drinking water contaminants are transition metals which are most commonly analyzed using spectroscopic methods, such as AAS, ICPAES, or ICPMS.[11] However, IC is a USEPA-approved method for the analysis of the ammonium cation, sodium, potassium, calcium, and magnesium

Figure 11 Separation of ammonia and alkali/alkaline earth cations. Conditions: column, Dionex® IonPac® CS12A; eluent, 18 mM methanesulfonic acid; flow rate, 1.0 mL min^{-1}; detection, suppressed conductivity with a cation self-regenerating suppressor (CSRS) operated at 100 mA in recycle mode; injection volume, 25 µL; solutes, 1 = lithium (1 mg L^{-1}), 2 = sodium (4 mg L^{-1}), 3 = ammonia (5 mg L^{-1}), 4 = potassium (10 mg L^{-1}), 5 = rubidium (10 mg L^{-1}), 6 = cesium (10 mg L^{-1}), 7 = magnesium (5 mg L^{-1}), 8 = calcium (10 mg L^{-1}), 9 = strontium (10 mg L^{-1}), 10 = barium (10 mg L^{-1}).

in rain water and wet precipitation, and provides a straightforward method for the simultaneous analysis of these cations.[19] Also, the ISO has recently published an ISO Method for the simultaneous determination of dissolved alkali and alkaline earth cations, ammonia, and manganese in water and wastewater using IC.[51] Figure 11 shows an example of a typical separation of alkali and alkaline earth cations and ammonia obtained using a Dionex® CS12A column with an eluent of methanesulfonic acid and suppressed conductivity detection.

IC is particularly beneficial for the simultaneous determination of cations plus ammonia in wastewaters containing amines, as these compounds can interfere with the conventional colorimetric or ISE methods used for ammonia analysis. Recently, an ASTM method based on IC has been proposed for the analysis of ammonia, sodium, potassium, calcium, and magnesium in reagent, drinking, surface, and groundwater and mixed industrial and domestic wastewater. This method uses a Dionex® CS15 column which has crown ether functionalities incorporated into the stationary phase to provide maximum resolution of ammonia and the

Figure 12 Determination of ammonia in industrial wastewater. Conditions: column, Dionex® IonPac® CS15; temperature, 40 °C; eluent, 10 mN sulfuric acid/10% methanol; flow rate, 1.2 mL min^{-1}; detection, suppressed conductivity with a CSRS operated at 100 mA in external water mode; injection volume, 25 µL; solutes, 1 = sodium (100 mg L^{-1}), 2 = ammonia (0.025 mg L^{-1}), 3 = calcium (not quantitated).

adjacent sodium peak. The use of this column with an eluent of 13 mN sulfuric acid and suppressed conductivity detection can achieve an MDL for ammonia of 1.0 µg L^{-1} using a 100 µL injection loop.[52] Figure 12 shows the application of this column for the determination of ammonia in industrial wastewater containing a large excess of sodium.

5.2 Natural Waters

In addition to being approved for a number of drinking-water and wastewater analyses, IC is also widely used for analysis of natural water samples. Many of the regulatory methods described in section 5.1 are also validated for natural waters, such as ground and surface waters. Natural waters encompass a wide variety of sample matrices, including: rain and acid rain; mineral spring waters and other groundwaters; surface waters (such as river, stream, lake, and pond waters); soil pore waters; runoff waters; snow, hail, and sleet; ice and ice cores; well and bore waters, etc. There are few regulations governing the analysis of such samples, hence a great diversity of IC methods are applied to a much wider range of analytes than in the highly regulated area of drinking water and wastewater analysis.

Although the key regulatory methods which use IC were described in the preceding pages, it is beyond the scope of this article to describe all of the applications of IC to natural-water analysis. Good overviews of the early use of IC for environmental applications are available,[9,10] and two very comprehensive listings of environmental analyses using IC were published in

1990.[5,53] In addition, proceedings of the International IC Symposium, published annually since 1991 by the *Journal of Chromatography*, contain excellent summaries of current developments and applications of IC for environmental and other analyses.

The analysis of rain water and acid rain is one of the more important applications of IC. The determination of ionic components in rain waters by IC is frequently used to estimate the effects of acidification on the natural and urban environments caused by acid rain.[54] The major ionic components of acid rain consist of the hydronium ion, sodium, ammonium, potassium, calcium, magnesium, and chloride, nitrate, and sulfate. Clearly, separate analyses using the separations presented in Figures 1 and 11 would provide the major components of an ion balance for an acid rain, once the sample pH had been measured. USEPA Methods 300.7 and 300.6 are based on similar, although somewhat dated, methods for the determination of these cations and anions, respectively, in acid rain and rain water.[19,55]

Many researchers have developed methods that enable the simultaneous determination of both anions and cations in rain waters and atmospheric aerosols, with perhaps the most comprehensive approach involving an automated quadruple IC system to perform isocratic anion, gradient anion (with and without sample preconcentration), and gradient cation separations using

Figure 13 Simultaneous determination of anions and cations in acid rain. Conditions: column, Tosoh® TSKgel OA-PAK; eluent, 5 mM tartaric acid/7.5% methanol; flow rate, 1.2 mL min^{-1}; detection, nonsuppressed conductivity; injection volume, 100 μL; sample, acid rain from Nagoya, Japan; solutes, 1 = sulfate, 2 = chloride, 3 = nitrate, 4 = sodium, 5 = ammonia, 6 = potassium, 7 = magnesium, 8 = calcium. (Reprinted from K. Tanaka, K. Ohta, J.S. Fritz, S. Matsushita, A. Miyanaga, 'Simultaneous Ion-exclusion Chromatography Cation Exchange Chromatography with Conductometric Detection of Anions and Cations in Acid Rain Waters', *J. Chromatogr.*, **671**, 239–248, Copyright (1994) with permission from Elsevier Science.)

a single sample injection.[56] Tanaka et al. developed a less complex approach that enables the simultaneous determination of anions and cations in acid rain based upon a simultaneous ion-exclusion–cation-exchange separation and non-suppressed conductimetric detection.[54] Figure 13 shows an example of a chromatogram of anions and cations in rain water obtained using this approach.

Gradient elution is typically required to quantify all of the minor acid components of rain-water samples, as organic acid anions, such as formate, acetate, or methanesulfonate, are often present at low levels in rain-water samples.[57] Figure 14 shows an example of the resolving power that can be achieved with an hydroxide gradient using modern IC instrumentation, whereas Figure 15 shows the separation of inorganic anions and organic acids in rain water obtained using a borate gradient with a Dionex® AS11 column and suppressed conductivity detection. Gradient separations can be used to quantify a wide range of anionic solutes in complex water samples, such as hazardous-waste leachates. In addition to rain-water analysis, IC has also been used to analyze terrestrial waters and ice cores from pristine environments, such as Antarctica, in order to establish baseline levels of pollutants.[58,59]

The analysis of ground and surface waters is another common application of IC. The determination of inorganic solutes in waters from rivers, streams, lakes, and ponds is similar in complexity to the analysis of typical wastewater samples. Filtration followed by pretreatment with SPE cartridges to remove hydrophobic organic material is recommended when analyzing most ground and surface waters. Mineral waters are typical examples of natural groundwaters which are commonly analyzed by IC. These samples can significantly differ in both total mineralization and also chemical composition.[60] IC has been shown to be applicable to the determination of over 98.6% of the total cation composition and over 98.9% of the noncarbonate anion composition of mineral waters.[61] Similarly, IC is also frequently applied to the determination of inorganic ions in surface waters. Figure 16 shows the analysis of inorganic anions in lake water from Salt Lake in Utah obtained using an AS4A column and suppressed conductivity detection.

IC tends to be more commonly utilized for the determination of metal species in natural waters than in drinking-water and wastewater samples. The ability of IC to quantify different oxidation states, such as Fe(II) or Fe(III); and stable metal complexes, such as metallocyanides, or both inorganic and organic arsenic species is of great benefit in determining the fate, transport, and toxicity of metals in natural waters.[14,62] Figure 17 shows an example of the determination of low parts per billion levels of metal cations in

Figure 14 Hydroxide gradient separation of inorganic and organic acid anions. Conditions: column, Dionex® IonPac® AS11; eluent, deionized water/sodium hydroxide gradient; flow rate, 2.0 mL min^{-1}; detection, suppressed conductivity; solutes, 1 = isopropylethylphosphonate (5 mg L^{-1}), 2 = quinate (5 mg L^{-1}), 3 = fluoride (1 mg L^{-1}), 4 = acetate (5 mg L^{-1}), 5 = propionate (5 mg L^{-1}), 6 = formate (5 mg L^{-1}), 7 = methanesulfonate (5 mg L^{-1}), 8 = pyruvate (5 mg L^{-1}), 9 = chlorite (5 mg L^{-1}), 10 = valerate (5 mg L^{-1}), 11 = monochloroacetate (5 mg L^{-1}), 12 = bromate (5 mg L^{-1}), 13 = chloride (2 mg L^{-1}), 14 = nitrite (5 mg L^{-1}), 15 = trifluoroacetate (5 mg L^{-1}), 16 = bromide (3 mg L^{-1}), 17 = nitrate (3 mg L^{-1}), 18 = chlorate (3 mg L^{-1}), 19 = selenite (5 mg L^{-1}), 20 = carbonate (5 mg L^{-1}), 21 = malonate (5 mg L^{-1}), 22 = maleate (5 mg L^{-1}), 23 = sulfate (5 mg L^{-1}), 24 = oxalate (5 mg L^{-1}), 25 = ketomalonate (10 mg L^{-1}), 26 = tungstate (10 mg L^{-1}), 27 = phthalate (10 mg L^{-1}), 28 = phosphate (10 mg L^{-1}), 29 = chromate (10 mg L^{-1}), 30 = citrate (10 mg L^{-1}), 31 = tricarballylate (10 mg L^{-1}), 32 = isocitrate (10 mg L^{-1}), 33 = *cis*-aconitate (10 mg L^{-1}), 34 = *trans*-aconitate (10 mg L^{-1}).

river water obtained after preconcentrating 40 mL of sample.[63]

5.3 Brines

The analysis of brines by IC is complicated by the high ionic strength and excess sodium chloride in the sample. Nevertheless, IC is frequently used for the analysis of inorganic solutes in natural-water brines, which include seawater, subsurface brines, geothermal brines, and very high salinity groundwaters. The analysis of major components, e.g. chloride and sulfate, in brines is relatively straightforward, only requiring a dilution before direct injection into the IC device.[64] However, the analysis of minor components in brines typically requires careful selection of analytical conditions, and a wide variety of approaches have been used for the analysis of these minor components. The use of IC for the analysis of anions in high salt concentration environmental waters has recently been reviewed by Singh et al.[65] In addition to the use of conventional suppressed IC, other approaches include: using sodium chloride as the eluent; sample pretreatment with Ag-form membranes and SPE cartridges; the use of heart-cut matrix elimination or preconcentration combined with matrix elimination; and the use of more selective detection methods, such as UV/VIS absorption, amperometry, postcolumn derivatization, and even ICPMS.[30,32,58,65–72]

The use of sodium chloride as an eluent combined with low-wavelength UV detection allows the determination of UV-absorbing anions, such as nitrate, iodide, and molybdate, in samples containing up to 20 000 mg L^{-1} of chloride without loss of chromatographic performance.[66] A similar approach with an eluent containing chloride and an ion-pairing reagent has been used for the analysis of thiosulfate and polythionates in natural saline waters.[68] Sample pretreatment with Ag-form SPE cartidges or membranes to reduce chloride is a commonly used approach to allow determination of minor anionic components in brines. Chloride precipitates as AgCl, although other halides are also removed to a significant extent using this approach and poor recoveries can

Figure 15 Determination of inorganic anions and organic acids in rain water using a borate gradient. Conditions: column, Dionex® IonPac® AS11; eluent, deionized water/sodium tetraborate gradient; flow rate, 1.0 mL min^{-1}; injection volume, 25 μL; detection, suppressed conductivity using an AMMS. (Reprinted from A.A. Ammann, T.B. Ruttimann, 'Simultaneous Determination of Small Organic and Inorganic Anions in Environmental Water Samples by Ion-exchange Chromatography', *J. Figure 16 Determination of anions in lake water. Conditions as for Figure 3, except: sample, water from Salt Lake, Utah; solutes, 1 = injection peak, 2 = fluoride (0.28 mg L^{-1}), 3 = chloride (142 mg L^{-1}), 4 = bromide (0.18 mg L^{-1}), 5 = nitrate (11.2 mg L^{-1}), 6 = phosphate (0.28 mg L^{-1}), 7 = sulfate (44 mg L^{-1}).

be obtained for nitrite.[30,32] Selective detection can be applied to the determination of specific ions; for instance, iodide has been determined in brine using pulsed amperometry at a silver working electrode after separation on a Dionex® AS11 column with an eluent of 50 mM nitric acid. Iodide could be quantified at 16 μg L^{-1} in 30% NaCl

Figure 17 Determination of metal cations in river water obtained using sample preconcentration. Conditions: column, Nucleosil® C_{18}; eluent, 2 mM octanesulfonate/0.35–0.5 M tartrate gradient; detection, UV/VIS at 510 nm after postcolumn reaction with 4-(2-pyridylazo)-resorcinol (PAR); sample, 40 mL river water preconcentrated; solutes, copper (5 μg L^{-1}), zinc (47 μg L^{-1}), lead (0.9 μg L^{-1}), nickel (7.2 μg L^{-1}), cobalt (1.8 μg L^{-1}), manganese (38 μg L^{-1}), magnesium (430 μg L^{-1}). after a 10-fold dilution and calibration using standard addition.[69]

Automated matrix elimination techniques have also been used to determine anions and metals in seawater samples. Nitrite, bromide, nitrate, and sulfate have been determined in brine using a heart-cut and recycling system. A unresolved cut of the sample containing

Figure 18 Determination of transition metals in seawater obtained using chelation concentration. Conditions: column, Dionex® IonPac® CS5; eluent, 35 mM pyridine 2,6-dicarboxylic acid; flow rate, 1.0 mL min^{-1}; detection, UV/VIS at 530 nm after postcolumn reaction with PAR; sample, 40 g seawater preconcentrated; solutes, iron (2.23 μg L^{-1}), copper (1.75 μg L^{-1}), nickel (1.34 μg L^{-1}), zinc (5.19 μg L^{-1}), manganese (1.85 μg L^{-1}). chloride and nitrite is trapped in a sample loop and reinjected onto an anion-exchange column using four- and six-port switching valves. This method permits a DL of 0.5 mg L^{-1} for nitrite in spiked seawater samples when using IC with suppressed conductivity detection.[70] The use of a highly cross-linked, iminodiacetate functionalized macroporous resin has been shown to selectively retain transition metals and lanthanides in the presence of high levels of alkali and alkaline earth metals.[71] A Dionex® MetPac™ CC-1 chelating concentrator has been used to concentrate transition metals from seawater, after which the metals are eluted, via an intermediate cation exchange concentrator, to a CS5 analytical column with a pyridine 2,6-dicarboxylic acid eluent. The separated metals were detected using UV/VIS absorption after postcolumn derivatization with PAR. A chromatogram obtained using this approach for the determination of transition metals in seawater is shown in Figure 18; a similar approach has also been used for the analysis of uranium and thorium in seawater.[72]

6 SOIL, SLUDGE, AND SOLID WASTE ANALYSIS

6.1 Soil and Soil Extracts

The analysis of inorganic ions in soils was amongst the earliest applications of IC.[9,10] As is also the case with natural waters, the ability of IC to quantify different metal oxidation states and stable metal complexes in soil extracts is beneficial in determining the fate, transport and toxicity of metals in soil.[14,62] Also, the analysis of total nitrogen, phosphorus, and sulfur, and their corresponding oxide anions, e.g. nitrite, nitrate, phosphate, and sulfate, is of importance in assessing soil condition and fertility.

Ideally, solutions injected for IC analysis should be low in organic materials, strong acids, and soluble salts; hence, many of the traditional methods used for the extraction or digestion of soils are not compatible with IC.[73] However, modifications of traditional extraction methods, including the use of water or more dilute salt solutions, have now been developed to allow the application of IC to soil analysis. In fact, a wide variety of extraction and dissolution conditions have now been used for soil samples prior to IC analysis. Table 7 gives examples of species which have been determined in soils by IC, and typical extraction and dissolution conditions used for sample preparation. The extraction process generally involves forming a slurry of a dried soil sample with approximately 10 times its mass of extracting solution. The slurry is then mixed using a suitable mechanical device, such as a rotation apparatus, wrist shaker, or sonic bath, for a period anywhere from 10 min to 24 h depending upon the sample.[17] The slurry is then centrifuged, filtered, pretreated using SPE if necessary, and injected into the ion chromatograph. Figure 19 shows an example of the determination of anions in an aqueous extract of a fertilized soil sample.

Alkali and alkaline earth cations can simply be extracted from soils using a dilute mineral acid.[73] However, transition metals are typically bound to complexing agents in soils and require more severe extraction conditions or total digestion of the sample. Metals, such as Cd, Cu, Mn, or Zn, have been determined in soils after

Table 7 Examples of typical extraction and dissolution conditions used for soil samples prior to IC analysis[5,8,73–78]

Extraction/dissolution conditions	Analytes determined
Aqueous extraction	Cl, NO_2, Br, NO_3, PO_4, SO_4

Conditions as for Figure 2 except: sample, (a) aqueous (1:7) soil extract (b) aqueous (1:7) soil extract spiked with 2, 5, 2, 2, 5, 20, and 20 mg L^{-1} of solutes 1–7, respectively; solutes (a) 1 = fluoride (0.6 mg L^{-1}), 2 = chloride (2.6 mg L^{-1}), 4 = bromide (0.3 mg L^{-1}), 6 = phosphate (25.5 mg L^{-1}), 7 = sulfate (8.2 mg L^{-1}), (b) 1 = fluoride (2.7 mg L^{-1}), 2 = chloride (6.7 mg L^{-1}), 3 = nitrite (1.8 mg L^{-1}), 4 = bromide (2.1 mg L^{-1}), 5 = nitrate (4.6 mg L^{-1}), 6 = phosphate (47.6 mg L^{-1}), 7 = sulfate (27.1 mg L^{-1}).

Figure 20 Determination of ferric and ferrous ions extracted from soil with 0.5 M HCl. Conditions as for Figure 18 except: eluent, 6 mM pyridine 2,6-dicarboxylic acid/50 mM acetic acid/50 mM sodium acetate; sample, 0.5 M HCl (1:10) soil extract; solutes, Fe(III) at 375 μM, Fe(II) at 239 μM. (Reprinted from M.Y. Ye, Y. Shen, C.C. West, W.G. Lyon,[77] 551–565 by courtesy of Marcel Dekker Inc.)

digestion in mixed nitric, perchloric, and hydrofluoric acids, followed by extraction using dithizone in chloroform, and destruction of the metal–dithizonate complex in nitric acid. The metals were chromatographed using a CS5 analytical column with a pyridine 2,6-dicarboxylic acid eluent and detected using UV/VIS absorption after postcolumn derivatization with PAR.[76] In some circumstances, metals can be released from soils using simple extraction procedures. The microbial reduction of Fe(III) to Fe(II) in soils and sediments is an important geochemical process and both hydrochloric acid (0.5 M) and ammonium oxalate (0.36 M) have been used to extract ferrous and ferric ions from these samples prior to IC analysis.[77] Figure 20 shows a chromatogram of Fe(III) and Fe(II) in a 0.5 M HCl extract of a soil sample.

6.2 Sludge, Leachates, and Solid Waste

The quantitation of inorganic ions in sludge, leachates and similar solid wastes by IC is similar in practice to the analysis of soil samples. Samples such as sludges, landfill, and solid (or hazardous) wastes are typically leached under aqueous conditions, then filtered and pretreated using SPE if necessary prior to injection. Although IC is most commonly applied to the analysis of anions in these sample types,[8,79,80] the determination of volatile fatty acids in landfill leachates is an important indication of the maturity of the waste deposit.[80,81] Low-molecular-mass organic acids can be separated either using an ion-exclusion separation or by gradient elution with an hydroxide eluent and suppressed conductivity detection. Figure 21 shows a chromatogram of volatile fatty acids in an immature landfill leachate, after 40 × dilution and acid treatment to remove carbonate, obtained using an ion-exclusion separation on a Dionex® HPICE/AS1 column.[80] Alternatively, gradient elution with an hydroxide eluent and suppressed conductivity detection can also be used for the determination of these volatile fatty acids by IC.[80,82]

The quantitation of metals in sludges and solid wastes also requires more severe extraction conditions or digestion of the sample, as is the case with soil samples. Total metals have been determined in sewage sludges by IC after dissolution in mixed nitric, perchloric, and hydrofluoric acids, followed by extraction using dithizone in chloroform, and destruction of the metal–dithizonate complex in nitric acid.[83] The metals were then chromatographed using a CS5 cation-exchange column and detected using UV/VIS absorption after postcolumn derivatization with PAR. Metals, such as Cr(III), Al(III), and Fe(II), have been analyzed in tannery sludges after extraction with sulfuric acid. The dried sludge samples were contacted for 24 h in concentrated sulfuric acid (1:20 ratio), then filtered, diluted, and passed through

Figure 21 Determination of volatile fatty acids in immature landfill leachate. Conditions: column, Dionex® HPICE/AS1 (high-performance ion chromatography exclusion–anion separator 1); eluent, 1.0 mM octanesulfonic acid; flow rate, 2.0 mL min^{-1}; detection, suppressed conductivity with an AMMS/ICE (anion micro-membrane suppressor/ion chromatography exclusion) suppressor; injection volume, 50 μL; sample, aqueous (1 : 40) extraction of immature landfill leachate treated with octanesulfonic acid to remove carbonate. (Reprinted from D.A.C. Manning, A. Bewsher, 'Determination of Anions in Landfill Leachates by Ion Chromatography', *J. Chromatogr.*, **770**, 203–210, Copyright (1997) with permission from Elsevier Science.)

XAD-7 resin to remove organic matter.[84] The metals were derivatized with 8-hydroxyquinoline and the neutral complexes separated on a C_{18} reversed-phase column and detected using UV/VIS absorption after postcolumn reaction with PAR. Recoveries in the range of 64–80% were obtained for Cr(III), Al(III), and Fe(II) in the sludge samples.[84]

Sludges and solid-waste samples can also prepared for analysis by IC using combustion methods. USEPA Method 9056 is applicable to the determination of common inorganic anions in solid-waste combustion extracts.[23] The weighed sample is placed in a sample cup and combusted in a Parr bomb containing oxygen under pressure. Released acid gases are trapped in a dilute carbonate/bicarbonate solution which can be analyzed for anions using an anion-exchange column with a carbonate/bicarbonate eluent and suppressed conductivity detection. The method is applicable to the determination of anions at levels greater than 500 mg L^{-1} in solid wastes, virgin and used fuel oils, fuels, and related materials.[23]

7 QUALITY ASSURANCE

QC is an essential part of environmental analysis when it comes to generating reliable results using IC, or any analytical method. A great deal of literature is available in the area of quality management and the subject of QC in environmental analysis is covered in detail in the article **Quality Assurance in Environmental Analysis**; the specifics of quality assurance in environmental analysis have also been described elsewhere.[85] In addition, USEPA Methods contain detailed (and mandatory) QC sections specific to the method of analysis. For instance, USEPA Methods 300.0 and 300.1 provide detailed instructions on QC procedures to be implemented when analyzing inorganic anions and DBP anions in environmental samples using IC.[22,16] A example of the requirements of a typical QC section contained in an IC method intended for environmental analysis is detailed in Table 8.[86]

Table 8 Typical QC section of an IC method used for environmental analysis[86]

QC procedure	Intent of procedure
IDP	Analysis of seven replicates of IDP solution to demonstrate laboratory (or operator) proficiency using the test method
Initial calibration verification using CVS	Run CVS to check calibration standards and acceptable instrument performance
Run one CVS with each sample batch. A batch is typically defined as somewhere from 10 up to a maximum of 20 samples	Ongoing verification of previously established calibration curves; analyte concentrations to fall within acceptable limits (typically ±15% known value)
Run one reagent blank with each sample batch	Ongoing check for contamination introduced by the laboratory or method
Run one QCS with each sample batch	The analyte recoveries of the QCS should fall within control limits of $x \pm 3S$, where x is the mean recovery and S is the standard deviation
Run one matrix spike with each sample batch	Ongoing test of method recovery
Run one matrix duplicate with each sample batch	Ongoing test of method precision
Additional QC	Any laboratory may perform additional QC as desired or appropriate to their own internal quality program

CVS, calibration verification standard; IDP, initial demonstration of performance; QCS, quality control sample.

An ion-selective electrode (ISE) is an electroanalytical sensor that produces a potential whose magnitude is dictated by the activity of a small number of ions. The signal is generated by selective partitioning of a charged analyte across the sample–electrode interface. These sensors allow a wide range of environmental pollutants to be detected and quantified rapidly, sensitively and selectively.[1] The ideal ISE can be inserted into the sample and will display the result of the chemical analysis within a few seconds with high precision and selectivity. Often no sampling, dilution or reagent addition is required, and changes in the analyte concentration or activity can be displayed in real time. Beyond the classical glass pH electrode invented in the early 1900s, the field now includes electrodes with several selective membranes for both sensing analytes and eliminating interferences, as well as ion-selective field-effect transistors (ISFETs). These new sensing approaches have greatly extended the range of environmentally relevant molecules that can be measured, and sensors exist for environmental pollutants as diverse as atmospheric carbon dioxide and radionucleotides in highly acidic solutions.

1 INTRODUCTION, OPPORTUNITIES AND ADVANTAGES

The technological development of the past century has seen a dramatic rise in emissions of anthropogenic pollutants. As a result, environmental analysis has become an area of intense interest for scientists and the public alike. The field has evolved, with the growing concern for the welfare of the environment requiring that qualitative and quantitative information on the nature, concentration and temporal changes in pollutants be available. Environmental monitoring is often mandated by legislation that places limits on allowable pollutant levels in soil, air and water samples. Furthermore, the financial penalties of ''polluter pays'' legislation make it essential for industrialists to continuously monitor their environmental impact. The challenge for analytical scientists is to provide suitable sensors for analysis of environmental samples in a sensitive, reproducible, rapid and accurate manner. This information is then applied to risk analysis, environmental impact studies and as a guide for remedial action. As shown in Table 1, these demands have led to the development of many important analytical approaches. Sensors have a significant role to play since they can be used, often on-site, to rapidly identify the type and concentration of pollutants. The goal of the analysis can range from preliminary, qualitative, field-screening to exposure assessments, time-dependent studies, speciation, etc. that require quantitative, dynamic information across a wide range of concentrations. Organic, inorganic and biological materials must be catered for and the impact of a wide range of sample matrices and interferences on the performance of the

Table 1 Analytical methods for environmental monitoring of common pollutants

Chemical pollutant	Analytical technique
Carbon dioxide	IR spectroscopy, ISE
Carbon monoxide	IR spectroscopy
Nitrogen oxides (NO_x)	CL, ISE
Methane	IR spectroscopy, GC
Ozone	CL
Sulfur dioxide	Flame photometry, sulfonation rate by spectroscopy, ISE
Elemental	AAS, AES, XRF
Organics	UV/VIS spectroscopy, TLC with fluorescence spectroscopy, GC
F^-, Cl^-, NO_3^-, CN^-, NH_3, etc.	ISE
Metals	AAS, adsorptive stripping voltammetry, ISE

IR, infrared; CL, chemiluminescence; GC, gas chromatography; AAS, atomic absorption spectroscopy; AES, Auger electron spectroscopy; XRF, X-ray fluorescence; UV/VIS, ultraviolet/visible; TLC, thin-layer chromatography.

method assessed. Many of the pollutants detailed in Table 1 cause concern even when their concentrations are at the micromolar level. Thus, environmental analysis is often characterized by the need to measure trace levels, while demanding that the analytical technique has a high degree of selectivity, sensitivity, precision and accuracy.

Potentiometry fulfills these requirements for several species that pollute water, soil and air samples. The technique is distinguished by its versatility and simplicity, and the following list highlights some of the main advantages.

- **Portability:** the sensors and instrumentation are physically small, simple, and are often sufficiently robust to allow on-site monitoring of pollutants.
- **Sensitivity and dynamic range:** the logarithmic response of ISEs gives rise to a broad dynamic range in comparison with other analytical techniques such as spectroscopy. One reason why ISEs are especially attractive for environmental monitoring is that analytes can be determined over a wide range of concentrations using the same equipment with minimum changes in the analytical method.
- **Established technology:** the ISE is possibly the earliest example of a chemical sensor; preliminary reports of the pH electrode were made in 1906 by Cremer and subsequently in 1909 by Haber and Klemensiewicz who carried out systematic studies of the glass electrode's response.[2,3] Commercial production of the pH electrode commenced in the 1930s when Corning produced their $NaO-CaO-SiO_2$ glass electrodes. Research over the following decades improved the glass composition for pH analysis and also led to the production of other ion-selective glass electrodes. Other membrane systems have been developed in addition to glass, and ISEs are now firmly established as the most common chemical sensors.
- **Low reagent demand:** small volumes of solvents or reagents are required to perform an analysis.
- **Ease of use:** nonspecialists can be quickly trained to operate and diagnose the performance of the sensors and instrumentation. Moreover, the data can be easily processed to extract quantitative information.
- **Multianalyte capabilities:** multiple sensors can be incorporated within a single device, either to improve the reliability of the analytical information or to allow the concentration of several target analytes to be measured within a single sample.
- **Continuous measurement:** with careful design, ISEs and ISFETs can be fabricated to provide meaningful information on the second and millisecond timescales. Therefore, while their use as detectors in chromatography is not especially widespread, they can be used in flow injection analysis (FIA) to achieve high sample-throughput and automated screening of samples.

2 PRINCIPLES

2.1 Background

An ISE is a potentiometric sensor that responds to the activity of certain ions. Figure 1 shows a general scheme for the measurement process. In ISEs, a selective membrane separates the internal reference solution and the analyte. Irrespective of whether the membrane is glass, a poly(vinyl chloride) (PVC) film containing an ionophore or a single lanthanum fluoride crystal, its function is to selectively exchange ions at the solution–membrane boundary. Ion exchange results in the formation of a potential difference which is measured using a high-input impedance voltmeter. The high-input impedance means that the voltmeter draws essentially no current through the electrochemical cell and the cell potential is measured under conditions that are very close to equilibrium.

2.2 Theoretical Considerations

For an ideal ion-specific membrane, the magnitude of the potential developed is related to the activity of a single ion in solution and is given by the Nernst equation (Equation 1)

$$E = E_{\text{constant}} \pm \frac{RT}{zF} \ln[a_i] \qquad (1)$$

Figure 1 Typical ISE measuring system, including an ISE with a selective membrane separating an internal reference electrode from the sample solution and an external reference electrode against which the transmembrane ISE potential is measured.

Figure 2 Typical ISE calibration curves. Curve 1 represents the situation found in the absence of interferences while curves 2 and 3 correspond to increasingly higher interference concentrations.

where E_{constant} is the cell constant, a_i is the activity of the ion in solution i, and z is the charge on the ion. For an ideal membrane, the slope would be 59.16 mV dec^{-1} for a univalent cation at 25 °C.

In reality, all electrodes are selective rather than specific and ions other than the primary ion contribute to the observed potential. These ions represent interferences to the measurement. Equation (2) describes the Nickolskii–Eisenmann equation that accounts for these interferences to the ISE response,

$$E = E_{\text{constant}} \pm \frac{RT}{z_j F} \ln \; a_{ik} + \sum K_{jkl}^{\text{pot}} a_{il}^{(z_k/z_l)} \qquad (2)$$

where a_{ik} is the activity of the primary ion in solution i, a_{il} is the activity of any interfering ion l, z_k and z_l are the charges on the primary and interfering ions, respectively, and K_{jkl}^{pot} is the selectivity coefficient of the electrode j against the interfering ion l. The empirical selectivity coefficient is unique to a particular cell and measurement conditions. The summation term of Equation (2) indicates how well the ISE can discriminate between the primary ion and interferences. The smaller the value of K_{ijl}^{pot} the more selective the membrane. An ideal membrane would have $K_{ijl}^{\text{pot}} = 0$ for all nonprimary ions and the Nickolskii–Eisenmann equation (Equation 2) would reduce to the Nernst equation (Equation 1). Typically a log scale is used to express the selectivity coefficients since ions that are dissimilar to the primary ion (principally through size and charge differences) will have selectivity coefficients close to zero, while similar ions may have K_{ijl}^{pot} close to unity. As illustrated in Figure 2, the concentration of interfering ions has a significant effect on both the linear calibration range and the limit of determination. Effects of this kind are especially important in environmental analysis, not only because low detection limits (DLs) are often essential, but because the absolute concentrations of interferences may be high.

To reduce the influence of interferences, one seeks to use ISEs that exhibit the smallest values of the selectivity coefficient and hence $K_{ijl}^{\text{pot}} a_j$. For many environmental samples, the background composition does not vary greatly from sample to sample. Thus, it is possible to use Equation (3) to estimate the maximum allowable value of the selectivity coefficient if the interferences are not to introduce error in the measured value of the primary ion activity, a_l, larger than P_{ij} percent

$$K_{ij}^{\text{pot}}(\max) = \frac{a_i(\min)}{[a_{ij}(\max)]^{n/z}} \times \frac{P_{ij}}{100} \qquad (3)$$

where $a_i(\min)$ is the lowest expected activity of the primary ion and $a_{ij}(\max)$ is the highest expected activity of the interferent. It may be possible to correct the responses of ISEs that fail to achieve the desired accuracy using numerical procedures.[4]

2.3 Dynamic Range

The dynamic or response range of an ISE defines the range of concentrations of the analyte ion to which the electrode will provide an analytically meaningful signal. Instrumental noise is intrinsic to any technique and often defines the lower limit of detection (LOD). This LOD may be described as the lowest concentration level of analyte that can be determined to be statistically different from the associated analyte blank. In practice, the LOD is the concentration of analyte which provides

a signal that is three times the standard deviation of the background noise. Typical ISEs for environmentally important analytes can be calibrated between approximately 10^{-5} and 10^{-1} M. The dilute end of this scale falls within the trace analysis range since 10^{-5} M corresponds to sub-parts per million (milligrams per kilogram) levels for simple anions and cations. It is sometimes possible to achieve even lower DLs by serial dilution of standards. However, use of ion buffers is an approach that can dramatically extend the calibration ranges of ISEs. For example, in the case of the fluoride sensor the typical lower calibration limit of 10^{-5} M can be pushed down to almost 10^{-10} M by using ion buffers containing Zr(IV), Th(IV) and La(III).[5]

Bakker has made significant contributions to improve the selectivity and sensitivity of ion-selective potentiometric and optical sensors.[6,7] In particular, Mathison and Bakker recently reported on the effect of transmembrane electrolyte diffusion on the DL of carrier-based potentiometric ISEs.[8] This work emphasizes the importance of considering the effects of both extraction and diffusion processes, e.g. the presence of lipophilic anions in the inner electrolyte solution increases the LOD owing to increased extraction into the membrane. Stirring the sample decreases the DL because it increases the mass transport rate from the membrane surface to the bulk sample. Bakker et al. highlighted the fact that many ionophores which achieve only micromolar LODs in ISEs can realize picomolar DLs in optically based approaches.[9] In membrane-based ISEs, poor DLs may arise because of primary ions leaching from the internal filling solution into the sample. Sokalski et al. used an internal electrolyte with a low activity of the primary ion and a high activity of an interfering ion.[10] This filling solution establishes a concentration gradient in the membrane causing a constant flux of the primary ion toward the inner compartment. In this way, the passage of the primary ion into the sample is prevented. Using this innovative approach, Sokalski et al. were able to push the conventional LOD for a Pb^{2+} electrode from 4×10^{-6} M to 5×10^{-12} M!

3 PRACTICAL CONSIDERATIONS IN USING ION-SELECTIVE ELECTRODES FOR ENVIRONMENTAL ANALYSIS

3.1 Theoretical Versus Practical Analytical Conditions

While the conditions under which Equation (1) is obeyed are well defined, they are not necessarily fulfilled for practical analysis, which may cause measurement errors. For example, the Nernst equation is based on thermodynamic principles and is strictly applicable only to ideally reversible systems. However, potentiometric measurements are usually carried out at relatively short timescales, typically tens of seconds, and the Nernst (Nickolskii–Eisenmann) equation may be incorrectly applied to systems that are electrochemically irreversible over long periods. Moreover, besides the desirable ion-exchange reaction of the primary ion, there are several other processes that can contribute to the observed potential change, including redox, adsorption and membrane dissolution processes. The Nernst equation is not strictly applicable under these circumstances since it is valid only when one well-defined process occurs at an electrode. These secondary processes limit the range over which there is a linear dependence between potential and log activity.

3.2 Activity Versus Concentration

As discussed, the Nernst equation underpins the operation of ISEs. Therefore, it is the activity of ions in solutions that is actually measured. Measuring activity rather than concentration is advantageous for speciation purposes and for the study of acid–base, complexation and precipitation equilibria. However, it represents a significant disadvantage when the objective is to measure the total content, i.e. both free and bound forms, of an analyte in a sample. As discussed later, where the total content is important, the analyte must be released from the matrix by chemical pretreatment or distillation.

Determining the true activity of an ion in solution places considerable demands on the analytical procedures employed and the manner in which the samples are handled. In particular, the following conditions must be met.

(1) Chemical pretreatments, e.g. reagent addition, evaporation, dilution or freeze-drying must be avoided.

(2) The relationship between the signal and the ion activity must be known, i.e. the response function of the ISE under identical operating conditions must be determined so as to calibrate the response.

(3) The ISE should be specific, i.e. broad-band selectivity is not adequate, since the Nernst equation applies only to electrochemical systems involving a single well-defined process. The sample cannot be chemically modified to mask interferences.

Therefore, in the context of environmental monitoring, samples should ideally be analyzed in situ or directly read at a later stage without the addition of further reagents. This condition is often difficult or impossible to achieve because analytes that are of environmental interest must be preconcentrated, treated or digested prior to analysis because of low concentrations or matrix effects.

3.3 Calibration

The selectivity coefficient should equal the thermodynamic exchange constant for the transfer of an ion from solution into the selective membrane of the ISE under equilibrium conditions. Therefore, K_{ij}^{pot} is sensitive to both the selective element within the membrane, e.g. the host within a host–guest complex, and to the composition of the membrane. For example, for polymer-membrane-based ISEs, the solvent, plasticizer, polymer, and their respective concentrations, will all influence the transmembrane transport processes and hence the selectivity coefficients. Thus, there are several possible difficulties in both the calibration of individual sensors and comparing calibration data between separate devices.

First, changing ionic strength or variable liquid junction potentials may mean that the standard cell potential E^{o} is not constant over the entire concentration range. This shift will cause nonlinear calibrations or non-Nernstian slopes to be observed. Moreover, an incorrect membrane composition or redox-active impurities may mean that the characteristic electrode slope is not given by RT/zF. Processes such as slow partitioning of the analyte across the membrane/solution boundary, slow diffusion within the membrane or adsorption/desorption cause many ISEs to be slow to reach equilibrium. Failure to achieve global equilibrium means that the apparent selectivity coefficients become time dependent. This ''kinetic selectivity''[11] has been exploited in high-throughput FIA to improve the overall analytical performance, since the short timescale response is often more sensitive to the primary ion concentration than to interferences.[12]

Second, the composition of the membrane may change significantly over time. For example, leaching of the ionophore can be a particular problem for liquid-state electrodes where the ionophores and plasticizer are typically only physically entrapped within the matrix and tend to dissolve into the samples. Also, partitioning of water and lipophilic sample components into the ISE element will decrease the ionophore concentration within the membrane. The most significant effect of reducing the ionophore loading is not to decrease the sensor's sensitivity, but to degrade its ability to discriminate between ions. In the most extreme situation, the sensor loses the selectivity achieved by the incorporated ionophore and the sensor response will ultimately follow the Hofmeister or lyotropic series, e.g. for anions $SO_4^{2-} > CF_3COO^- > Br^- > ClO_4^- \approx NO_3^-$, and for cations $Na^+ > Ca^{2+} \approx K^+ > NH_4^+ > Li^+$.

Third, the electrode geometry and measuring conditions must be considered. For example, macroscopic and microscopic ISEs constructed using identical materials and techniques can exhibit differences in the observed potential of 10 mV or more. These differences may arise because the membrane properties depend on the electrode's size. However, there is some evidence that, as found for amperometric microsensors,[13,14] changes in the mass transport mode with size may influence the rate of ion exchange at the membrane/solution interface. These effects may give rise to an electrokinetic potential causing the electrode slope observed at a microelectrode to decrease relative to that observed for a macroelectrode.

Fourth, the background composition of the solutions must be constant if measurements or devices are to be compared. Here, our focus is on the possibility that the composition of the solution at the membrane/solution interface differs from that of bulk. These differences may arise simply because of the ion-exchange reaction itself[15] or because solvent or other components partition into, or out of, the sensing element.

3.4 Reference Electrodes

As illustrated in Figure 1, a reference electrode is an integral part of ISE measurements since it is against this potential that the ISE signal is measured. If operated incorrectly, then the reference electrode can act as a source of significant error. Temperature is an important variable in many environmental monitoring situations, especially for in situ water quality monitoring since the temperature can change dramatically with depth. However, the reference electrode potential is temperature dependent, e.g. for the traditional calomel reference electrode the reference potential shifts by approximately $0.7\,\text{mV}\,\text{K}^{-1}$. In real terms, this shift translates into a few percent relative error on measurements performed a few degrees apart. Also, as described by the Nernst equation (Equation 1), the ISE potential depends on the temperature. Therefore, it is important that the analysis and calibration temperatures are closely matched if accurate results are to be obtained. An alternative is to use a reference electrode, such as the $Zn/ZnCl_2$ system, whose potential is very insensitive to temperature.

It is also highly desirable to make the electrochemical cell as symmetrical as possible to minimize the effect of changes in temperature on the observed potential. This objective means not only that the same internal and external reference electrodes are used, but that the composition of the inner filling solution of the ISE matches the sample composition as closely as possible. Thus, in contrast to most reference electrode filling solutions where 6 M or even saturated solutions are commonly used, ISEs are often filled with a 0.1 M solution of the primary ion. This lower concentration within the internal filling solution also helps prevent contamination of the samples by leakage, e.g. in the case of chloride determination.

3.5 Response Time

Under special conditions, ISEs can respond rapidly to abrupt changes in the concentration of their primary ion around the midpoint of their calibration range, achieving 90% of the total potential change within 100 ms. However, typical ISEs respond much more slowly with equilibrium responses only being obtained after seconds or even tens of seconds.

3.6 Quality Control in Ion-selective Electrode Measurements

Quality control is an important issue when using ISEs for environmental analysis, to ensure accurate and reproducible results. A typical quality control system involves periodic confirmation of the ISE calibration by determining the concentration of a known, independently prepared sample. For example, immediately after an ISE is calibrated, an initial calibration verification (ICV) standard should be analyzed. The ICV contains a known concentration of the primary ion close to the midpoint of the calibration range and is prepared independently of the calibration standards. For acceptable performance, the ICV recovery must be between 90% and 110% otherwise the source of error must be identified and corrected. This verification standard is typically analyzed after every ten samples. If the ISE calibration has changed, all samples analyzed since the last acceptable continuing calibration verification (CCV) standard, must be re-analyzed. After each ICV and CCV sample analyzed, a reagent blank is often analyzed. This blank is frequently high-purity water but, if reagents are being added to the samples, then a 1 : 1 dilution of the buffer is often used. The objective in measuring the blank is to identify possible contamination of the samples. Spiking the samples is another common approach to ensure that quality measurements are performed. The spike concentration must be ten times the DL and the volume added must be negligible (less than or equal to one-thousandth of the sample volume). Spike recovery must be 75–125%, otherwise samples must be analyzed by performing standard additions.

4 TYPES OF ION-SELECTIVE ELECTRODES

All ISEs rely on a membrane to separate the analyte and reference solutions. Therefore, ISEs may be conveniently classified according to the nature of this membrane material. While the membranes may absorb solvent, ideally they are as immiscible as possible with their analyte solution. Hydrophobic organic liquid ion-exchange electrolytes, solid polyelectrolyte ion exchangers and solid ion-conducting electrolytes are the most frequently employed electrode membranes types. The best membranes are ionically conducting, for example solid or liquid electrolytes that contain substances which ionize depending on the membrane dielectric constant and extent of solvent penetration.

4.1 Solid-membrane Electrodes

The success of the pH glass electrode is without parallel in sensors. Although somewhat mechanically fragile, it resists a wide variety of sample media and, with the exception of hydroxide, is largely free from interferences. Moreover, pH-sensitive glass electrodes form the basis of many successful sensors for environmentally important gases including carbon dioxide, sulfur dioxide and nitric oxide. Thus, glass membranes represent an important class of solid-membrane ISEs. As illustrated in Figure 3, these ISEs have a thin glass membrane fused to the end of a glass or plastic body. The main body of the electrode contains an internal reference electrode, typically Ag/AgCl, and is filled with a solution that is usually the chloride salt of the primary ion. The membranes are primarily made from lithia, aluminosilicate or multicomponent glasses whose selectivity pattern depends on the composition of the glass. As shown in Table 2, excellent discrimination against common cationic species is achieved. There are no anion-selective glass membrane materials and glass membranes are primarily used for sensing of monovalent cations.

As illustrated in Figure 4, homogeneous membrane electrodes contain insoluble crystalline materials either

Figure 3 Schematic diagram of a typical glass electrode. The internal reference electrode is usually Ag/AgCl.

Table 2 Selectivity coefficients of some glass-membrane electrodes

Membrane	Log selectivity coefficients				
	H^+	Na^+	K^+	NH_4^+	Ag^+
NAS 11-18	10^3	1	10^{-3}	3×10^{-5}	400
NAS 27-04		0.1	1	0.3	

Figure 4 Diagram of (a) a solid homogeneous membrane electrode and (b) an electrode with a solid heterogeneous membrane.

as single crystals or as compressed powder pellets. An important example of an electrode of this type is the fluoride electrode. This electrode consists of a membrane of a single crystal of lanthanum fluoride doped with europium(II) fluoride to improve conductivity. The internal filling solution consists of 0.1 M NaF and NaCl, with an internal reference electrode of silver–silver chloride. This membrane only conducts fluoride but hydroxides may interfere with the measurement. Other homogenous membrane electrodes that have found significant use in environmental analysis include sensors for pollutants such as cadmium, cyanide and lead.

In contrast, heterogeneous membrane electrodes comprise an active crystalline material dispersed through another matrix, for example a polymer that improves the mechanical robustness of the sensor. However, plastics are electrical insulators and to achieve sufficient electrical conductivity the active ingredient must be present in high concentration. There are not many materials which can be easily prepared as single crystals and this approach to sensor design has extended the number of target analytes. Beyond dispersion in a polymeric matrix, pressed polycrystalline materials containing two or more inorganic salts, e.g. silver sulfide and iodide plus a binder to form an iodide selective ISE, are popular. Environmental analysis characteristically places heavy demands on the stability and durability of an electrode material, and, as shown in Table 3, many useful sensors have been developed using these approaches.

4.2 Liquid Ion-exchange Electrode

As illustrated in Figure 5, the traditional membrane of a liquid ion-exchange electrode consists of a homogeneous, organic, water-immiscible liquid absorbed into a millipore or nucleopore filter that incorporates mobile, ionic components. The mobile ionophores include compounds such as hydrophobic acids, bases or salts. Liquid membranes typically show Nernstian responses in the absence of interferences, usually for oppositely charged counterions to their own electrical charge. This design is more flexible than the solid-membrane materials considered in section 4.1 and ISEs sensitive to a much wider range of compounds can be fabricated using this arrangement, including K^+, Ca^{2+} and the environmentally important NO_3^- ions.[16] However, these ISEs have been largely superseded by other approaches, notably neutral carrier sensors, because of technical problems.

Table 3 Applications of solid-membrane ISEs to environmental analysis

Electrode type	DLs (M)	Interference	Environmental applications
Fluoride: Single crystal LaF_3	0.02 ppm	OH^-, Fe(III), Al(III)	Water quality, rain, air and vegetation. Drinking water fluoridation, minerals, soil, etching solutions containing H_2F_2
Chloride: AgCl, $AgCl/Ag_2S$ and Hg_2Cl_2/HgS	25 ppb	Br^-, I^-, CN^-, S^{2-}, Br^-, $S_2O_3^{2-}$, SCN^-	Water quality, seawater, treated sewage, wastewater, soil extracts
Bromide: $AgBr/Ag_2S$	50 ppb	OH^-, Cl^-, I^-, CN^-	Water quality
Cyanide: AgI/Ag_2S	5 ppb	S^{2-}, I^-	Industrial wastewater, galvanic baths, mineworks
Iodide: AgI and AgI/Ag_2S	12 ppb	OH^-, Cl^-, Br^-, CN^-	Water quality
Sulfide: Ag_2S	10 ppb	CN^-, I^-, CrO^{2-}, IO^{3-}	Industrial effluent, sewage, water quality, food and drinks
Cadmium: CdS/Ag_2S	0.1 ppm	Hg^{2+}, Ag^+, Cu^{2+}, Pb^{2+}, S^{2-}, Cl^-, I^-	Water quality, industrial effluents
Lead: PbS/Ag_2S	0.2 ppm	Hg^{2+}, Ag^+, Cu^{2+}, Fe^{3+}	Water and air quality, soil analysis, vehicular emissions
Copper: CuSe single crystal or CuS/Ag_2S	0.05 ppm	Hg^{2+}, Ag^+, Fe^{3+}	Industrial effluent, water quality

Figure 5 Diagram of a classical liquid-membrane electrode.

These difficulties include imperfect filling of the support membrane pores by the ionophoric liquid, leading to sample permeation into the internal filling solution that ''short circuits'' and fails to generate a measurable transmembrane potential. Also, the liquid membranes themselves tend to be somewhat unstable, becoming contaminated by lipophilic substances within the samples or mechanically dislodged from the support if mishandled.

Neutral-carrier ISEs are typically based on PVC in which a suitable electrically neutral ionophore, plasticizer and ion-exchanger are co-immobilized. The ionophores typically possess a polar cavity that contains electron-donating atoms or polar groups capable of interacting with the target ions. The stability of the complex, and hence the selectivity coefficient, is determined by a ''best-fit'' mechanism and the neutral carrier is more selective towards ions that best fit the molecular cavity. Larger ions will not be able to effectively penetrate the cavity, while smaller ions will interact with too few donor atoms to form stable complexes. The strength of binding must be carefully balanced, since while strong binding favors specificity, forming too strong a complex will lead to irreversible responses. The types of molecules used in neutral-carrier ISEs continues to expand, and include crown ethers,[17] calixarenes,[18,19] complex macromolecules, and antibiotics such as valinomycin[20] and nonactin.[21] Neutral-carrier ISEs are commonly used for ions such as Na^+, K^+, Li^+, NH_4^+, Ca^{2+}, Cs^+ and Ba^{2+}.

4.3 Gas-sensing Membrane Electrodes

Gas sensing is an extremely important aspect of environmental monitoring in areas ranging from smokestack emissions, notably for sulfur and nitrogen oxides, to carbon dioxide levels in ambient air. The earliest and most commercially successful gas-sensing probe is based on the Severinghaus electrode,[22] in which a glass pH-electrode is placed behind a gas-permeable membrane. Table 4 shows common gas-sensing electrodes that are important in environmental analysis. These electrodes differ from those described above in two important ways. First, they do not directly detect the target analyte. They are not true ISEs, but are complete electrochemical cells capable of indirectly determining the concentration of the target analytes using a conventional ISE that is internal to the cell. A popular approach to gas sensing is to analyze the by-products of the target chemical's reaction with the internal electrolyte, most commonly by monitoring pH changes in the cell. Second, because of the mode of operation, gas-sensing electrodes employ two membranes; the first allows the gas of interest to permeate into the electrochemical cell, and the second selectively generates the ISE potential.

Figure 6 shows a schematic of a typical gas-sensing probe. The probe comprises an outer gas-permeable membrane which prevents nongaseous interferences from accessing the inner cell. Once dissolved in the inner-cell filling solution, the analyte establishes a chemical equilibrium with the electrolyte and the products are then detected by the internal ISE. Gas-sensing probes are often highly selective since many interferences are removed by the gas-permeable outer membrane and the analyzing ISE is typically a highly selective pH electrode. The main disadvantages of such sensors are their poor long-term stability and their long response times, associated with the slow rate of gas diffusion across the membrane.

The second type of gas-sensing ISE is the air-gap electrode. In this arrangement, the internal filling solution surrounds the internal ISE's surface as a thin film, and an air bubble replaces the outer gas-permeable membrane.

Table 4 Environmentally important gases that can be determined using an ISE

Analyte	Internal filling solution	Equilibrium reaction	Internal ISE
CO_2	$NaHCO_3$	$CO_2 + H_2O \longrightarrow H^+ + HCO_3^-$	pH
NH_3	NH_4Cl	$NH_3 + H_2O \longrightarrow NH_4^+ + OH^-$	pH or NH_4^+
NO_x	$NaNO_2$	$2NO_2 + H_2O \longrightarrow 2H^+ + NO_3^- + NO_2^-$	pH
SO_2	$NaHSO_3$ or $K_2S_2O_3$	$SO_2 + H_2O \longrightarrow H^+ + HSO_3^-$	pH
H_2S	Citrate buffer	$H_2S \longrightarrow H^+ + HS^-$	S^{2-}
HF	1 M H^+	$HF \longrightarrow H^+ + F^-$	F^-

Figure 6 Schematic diagram of a classical Severinghaus-type gas sensor.

This arrangement offers some advantages over the Severinghaus-type electrode in terms of sensitivity and response time. However, the electrode surface must not be allowed to dip into the analyte solution. The electrode is operated by passing the analyte close to the electrode surface, either in the form of a gas stream or, for solution samples, by stirring the sample solution rapidly in the presence of the electrode. The air-gap cyanide sensor is an example of such an arrangement and has important applications in atmospheric analysis.

4.4 Solid-contact and Coated-wire Ion-selective Electrodes

Solid-state electrodes of the types illustrated in Figures 7 and 8 that do not contain free-flowing liquids represent an important and growing area of ISE research. Unlike conventional solution filled sensors, their response does not depend on orientation, they can be more easily

Figure 7 Solid-contact electrode without any internal filling solution.

Figure 8 Coated-wire electrode.

miniaturized and they are mechanically flexible. As illustrated in Figure 8, coated-wire electrodes (CWEs) are formed by depositing a thin layer of material, often a polymer, onto the surface of an inert metal wire such as platinum or gold. CWEs have the advantages of rapid response, small size and suitability for temperature and noise compensation and for the manufacture of arrays. The difficulty with these sensors is that the potential that develops at the layer/wire interface can be unstable over long periods.

4.5 Arrays

Using a single sensor to determine the concentration of an analyte demands that it be extremely selective if its response is to be overwhelmingly dominated by a single ion. Combining several individual sensors within an array is attractive since it allows multicomponent analyses to be performed and provides the high-quality analytical information necessary to model the role of interferences. Accurate modeling of the array response may allow partially selective sensors to be used.[23] Moreover redundancy, i.e. having more than one sensor within the array that is capable of performing the analysis, leads to more reliable sensing systems. Beyond these issues, considerable attention is being paid to developing ''smart'' sensors with much improved abilities to process analytical information. A smart sensor exhibits the following characteristics:

- able to process information for automatic calibration or compensation of baseline drift
- can communicate with other sensors or devices
- adapts to changes in its environment, e.g. automatic temperature compensation
- performs self-diagnosis of performance.

With the exception of true liquid-membrane electrodes, all of the ISEs described can formally be integrated within a sensor array. However, those that employ fabrication procedures that can produce planar membranes, e.g. solid-state and neutral-carrier membranes, are the most amenable to producing arrays. Another important consideration in selecting ISEs for arrays is the stability of the calibration. Stability, rather than selectivity, is perhaps the single most important issue in sensor arrays. For example, a factorial design is preferred for calibration purposes requiring L^{f-1} solutions, where L is the number of levels (e.g. high and low concentrations) and f is the number of factors (e.g. four ions). Thus, to calibrate a four-electrode array using a two-level, four-factor design requires 32 solutions. Clearly, the sensor output must be stable during this calibration and subsequent measuring period if an accurate model is to be constructed. Highly selective sensors are not necessarily desirable since an artificially high concentration of the interferences must be used to sufficiently perturb the sensor response.

4.6 Ion-selective Field-effect Transistors

ISFETs[24–26] represent a hybrid of technologies from solid-state physics and electrochemistry. As shown in Figure 9, ISFETs employ conventional ion-selective membranes that either replace the gate of a metal-oxide field-effect transistor (MOSFET) or are placed in direct contact with the gate. The intense interest in these devices during the late 1970s and 1980s has decreased somewhat recently because of the problems in establishing a stable internal reference potential where the PVC membrane comes in contact with the field-effect transistor (FET) surface. Also, solid-state sensors tend to suffer from poor sensor-to-sensor reproducibility even within a single batch of devices, requiring that sensors be calibrated individually. However, better fabrication technologies, materials and visualization techniques promise to solve many of these problems.

Figure 9 Typical ISFET.

The main advantages of ISFETs are their small size; the fact that they are compatible with planar silicon-processing technology, allowing them to be cheaply mass-produced; the ease with which they can be incorporated into arrays; the rapidity with which they respond to changes in analyte concentration; and their low impedance which makes them much less sensitive to electromagnetic interference. Depending on the materials used in their construction, light exposure may need to be controlled to obtain accurate readings.

Similar to a metal-oxide semiconductor FET, in an ISFET electric current flows from the source to the drain via a channel. The channel resistance depends on the electric field perpendicular to the direction of the current and on the potential difference over the gate oxide. Therefore, the source–drain current, i_{ds}, is influenced by the potential at the oxide/aqueous solution interface. At a fixed source–drain potential (V_{ds}), changes in the gate potential can be compensated by modulation of the gate–source potential, V_{gs}. This adjustment should be carried out in such a way that the changes in V_{gs} applied to the reference electrode are exactly opposite to the changes in the gate-oxide potential. This is automatically performed by the ISFET feedback amplifier that allows one to obtain constant source–drain current. In this case, the gate–source potential is determined by the surface potential at the insulator/electrolyte interface.

When SiO_2 is used as the insulator, the chemical nature of the interface oxide is reflected in the measured source–drain current. The surface of the gate oxide contains OH^- functionalities, which will be in electrochemical equilibrium with ions in the sample solutions (H_3O^+ and OH^-). The hydroxyl groups at the gate-oxide surface can be protonated and deprotonated and thus, when the gate oxide contacts an aqueous solution, a change of pH will change the SiO_2 surface potential. Typical pH sensitivities measured with SiO_2 ISFETs are 37–40 mV per pH unit rather than the 59 mV per pH unit predicted by the Nernst equation.[27] However, significant improvements on this performance have recently been achieved by using pH-ISFETs based on silicon nitride and tantalum oxide gates. In the Si_3N_4 system, silanol and amine sites make the assembly sensitive to the solution pH, while in the Ta_2O_5 ISFETs, Ta–O sites provide the pH sensitivity and close to ideal Nernstian behavior is observed.[28]

The selectivity and chemical sensitivity of the ISFET are completely controlled by the properties of the electrolyte/insulator interface. Therefore, by immobilizing a suitable membrane on the gate oxide, solid-state sensors for a range of environmentally important analytes can be fabricated.

5 ION-SELECTIVE ELECTRODES IN ENVIRONMENTAL ANALYSIS

The application of ISEs to environmental analysis can be divided into two different approaches. First, solution-phase analysis, e.g. water and effluent analysis. Second, gas-phase analysis, e.g. smokestack emissions and airborne pollutants. Many environmental monitoring applications require dynamic information about changing sample compositions within relatively short periods of time. One useful approach to achieving a high sample-throughput is FIA and we first review its mode of operation.

5.1 Techniques: Flow Injection Analysis

Although their responses are often too slow for use as end-column detectors in chromatography, the selectivity of ISEs can be exploited to achieve a high sample-throughput using FIA. Continuous methods in environmental analysis offer significant advantages over more traditional batch methods. Most importantly, it provides a means of observing temporal changes in environmentally important agents and may offer advance warning of impending pollution.

As described in the seminal work of Ruzicka,[29] in the flow injection method a carrier stream is continuously pumped around an analytical manifold and reproducible volumes of sample are injected into the stream at selected intervals.[30] After passage through reaction structures in the analytical assembly, the product or unreacted sample is passed to the detector, producing a signal whose magnitude depends directly on the concentration of the analyte. Usually the carrier contains a low concentration of the analyte ion in order to stabilize the ISE membrane potential. As illustrated in Figure 10, since the sample plug contains a higher concentration of the analyte, the analytical signal is an unsymmetrical peak whose shape reflects the effects of hydrodynamics and the kinetics of ion uptake and release.

As illustrated in Figure 11, the ISE can be integrated into the analytical assembly in one of four ways, namely by a flow-through, flow-past, tangential or wall-jet regime. In the flow-through and flow-past approaches, the electrode membrane replaces part of the tubing through which the analyte stream is travelling. In the tangential approach, the sample and membrane are at an acute angle of less than 90°, while in the wall-jet method the sample stream approaches the membrane at 90° and is then dispersed at the sides.

Operating ISEs in flowing streams offers a number of advantages over a batch-type approach. The Nernst diffusion layer that exists close to the membrane/solution interface is highly reproducible and stable, giving improved response times and very reproducible signals. Contamination problems arising from leaking reference electrodes are eliminated since the reference can be placed downstream of the detection point. The carrier solution can be easily modified so as to optimize the selective response of the ISE, e.g. controlling the ionic strength, masking interferences, etc. FIA offers a high sample-throughput, e.g. the flow rate is typically 0.5–1.0 ml min^{-1} and a 100 µl sample stays in contact with the membrane for only 6 s. Provided that the return to baseline is rapid, throughputs of 120 samples per hour or even higher may be achieved. Table 5 contains some examples where ISEs coupled to FIA have been exploited in environmental analysis.

FIA/ISE systems have been developed for use without a requirement for a preceding separation step. For example, copper has been determined in tap water

Figure 10 Typical FIA/ISE peak. The injection is made when the membrane is in equilibrium with the carrier solution. During the period labeled (a), the ISE potential increases rapidly owing to the boundary potential. A pseudo-steady-state situation is reached at the top of the peak (b). As the plug leaves the detector (c) and the membrane-carrier equilibrium is re-established, the potential returns to the baseline.

Figure 11 Different flow regimes used in FIA/ISE systems: (a) flow-through, (b) flow-past, (c) tangential and (d) wall-jet assemblies.

Table 5 FIA with ISE detection for environmental analysis

Analyte	Matrix	Electrode/membrane	Cell	Other features	Refs.
K^+	Soil	Valinomycin/di(iso-octyl)fatty acid ester/potassium tetra(4-chlorophenyl) borate/PVC	Tubular	Addition of the main ion to the carrier stream	31
Ca^{2+}	Tap water	(−)-(*R*,*R*)-*N*,*N* bis[11-(ethoxy-carbonyl)undecyl]-*N*,*N*′-4,5-tetramethyl-3,6-dioxaoctane-diamide/diethyl *N*,*N*′-[(4*R*,5*R*)-4,5-dimethyl-1,8-dioxo-3,6-dioxaoctamethylene]bis(12-methylaminododecanoate)(ETH 1001)			32
Ca^{2+}	Tap, river, and lake water	Calcium bis{bis-[4-(1,1,3,3-tetramethyl-butyl)phenyl]phosphate}/PVC	Tubular	Surfactants present	33
NO_3^-	Seawater	Commercial		In parallel with Na^+, K^+, Ca^{2+}	34
NO_3^-	Soil solution	Valinomycin/ETH 1001/tetradodecyl ammonium nitrate	Miniature	Multi-ion sensor cell	35
		Mobile carrier/PVC	Tubular	No inner reference solution	36
		Commercial	Tubular	Process control	37
CN^-	Industrial	CN^- sensor	Variable volume		38
S_2^{2-}	Natural and wastewater	AgS/Ag-based conductive epoxy glue	Tubular		39
	Sewage effluent	Commercial		Peroxide inhibition of interferences	40
	Effluents	Ag_2S	Tubular	Favorable comparison with commercial cascade electrode	41
F^-	Rainwater	Commercial		Limitation of linear response in FIA	42
Cl^-	Soil solution	Ag/AgCl	Miniature	Computer-controlled data acquisition	35
	Natural and wastewater	Coated solid-state Ag/AgCl	Tubular	High sample-throughput	43, 44
Br^-	Soil solution	Coated solid state sensor	Tubular	Primary ion added to carrier stream	45

using a detection system comprising two Cu^{2+} selective electrodes as indicator and reference.[46] In common with most FIA/ISE analyses, a relatively high concentration of electrolyte (0.1 M KNO_3 in this case) was added to the carrier stream to ensure a steady baseline. The results obtained compare well with those observed using a standard spectrophotometric approach. Moreover, as highlighted in Table 5, the primary ion is frequently added to the carrier stream, e.g. 5000 ppm cyanide was added to the carrier stream during the determination of cyanide in wastewater.[47]

ISEs have also been used as detectors in FIA following a separation step to ensure optimum sensor performance by efficiently eliminating interferences. Ion-exchange columns have also been incorporated with the twin objectives of improving sensitivity (pre-concentration step) and selectivity (separation step). For example, a porous glass column coated with 8-quinolinol has been used to preconcentrate copper.[48] Interferences from trace metal can be removed on-line using chelating ion-exchangers. This approach achieves DLs that are between 10^{-7} and 10^{-8} M.

Flow injection also lends itself to multianalyte determinations by incorporating as many ISEs as there are analytes into the detection manifold. The sensors are often placed in series. However, careful attention must be paid to achieving minimum dispersion and dead volume, i.e. high fluid velocities and well-defined sample plugs across each sensor should be employed. Multi-ion analyzers have been constructed to monitor potassium, calcium, nitrate and chloride in soil extracts, and to determine sodium, potassium, calcium, bicarbonate, nitrate and chloride in drinking water.[35]

While FIA certainly has the great advantages of high sample-throughput and highly reproducible sample handling, there are some difficulties in using ISEs as

detectors in FIA. First, as discussed in section 2.2 dealing with theoretical issues, the analyte often does not reach global equilibrium with the sensing element even for slow flow rates or stopped flow approaches. Since kinetic selectivity[49] often depends on the analyte concentration it causes plots of potential vs logarithm of analyte activity to become nonlinear. Therefore, slow transport or other kinetic difficulties can be a source of calibration errors because the rate at which equilibrium is achieved differs between standards and samples. Second, when the dilute electrolyte carrier solution moves along the ISE surface, excess charges outside the double layer are carried along by the flow, causing a streaming potential. The magnitude of the streaming potential depends on the ionic strength of the carrier, the solvent viscosity and the flow rate. It can be reduced by either stopping the flow to make the measurement or by using a carrier of high ionic strength. Another important technical consideration is contamination of the electrodes by components within the samples, e.g. highly lipophilic species in the case of neutral carrier ISEs. However, the short residence time of the sample compared with batch-type measurements usually means that this is a minor problem.

5.2 Water-based Monitoring

The late twentieth century has seen a dramatic increase in the consumption of water for domestic, agricultural and industrial purposes. As water is recycled, it is important to confirm that the water quality is acceptable and that it will not contaminate other stocks, e.g. reservoirs, storage tanks, rivers, lakes, etc. Historically, water analysis often involved simply checking the pH and biological oxygen demand, with the total salt concentration being estimated from the solution conductivity. However, this nonspecific information is becoming increasingly inadequate as limits are set for acceptable discharge levels for a wide variety of analytes ranging from heavy metals to anions. Potentiometry plays an important role in providing direct information about the concentrations of many important pollutants in potable and naturally occurring bodies of water.

5.2.1 Metallic Species

The ability to determine in situ the distribution of metal species using a simple, rapid technique is extremely valuable since the toxicity, transport and ultimate fate of the metallic species depends not only on the identity of the species in question but also on their oxidation state. Current environmental protection methods, e.g. those that have been evaluated and approved for use by the United States Environmental Protection Agency (USEPA),[50] focus heavily on the use of AAS for the determination of metals in the environment. However, AAS destroys the sample, requires a separate protocol for each metal, cannot differentiate valence states or species, is expensive and time-consuming and has difficulty in simultaneously determining the concentration of several metals. Therefore, there is growing interest in using ISEs for the environmental monitoring of metallic species.

5.2.1.1 Mercury Classical mercury ISEs exhibit linear calibration ranges in the 10^{-5}–10^{-7} M range. However, the unbound Hg^{2+} concentration is often in the 10^{-9} M range in natural environments. Therefore, highly sensitive sensors that are almost completely mercury specific, or whose responses can be corrected for the effects of interferences, are required. Epoxy-based ISEs have been developed that are capable of determining Hg^{2+} concentrations at the 10^{-14} M level, making them useful tools for the determination of both free and inorganic-bound mercury in natural waters.[51] However, Fe^{3+} represents a significant interference, not only because of poor selectivity, but also because Fe^{3+} can be present at high concentrations in environmental samples.

Host molecules capable of selectively binding heavy metals have been immobilized within PVC membranes to form polymeric ISEs. For example, calixarenes have been synthesized that incorporate soft donor atoms, such as nitrogen and sulfur, within the ion-binding cavity to create hosts for ISEs that are sensitive to Hg(II), Ag(I), Cu(II) and Pb(II).[52] A combination of the correct number and location of soft donor atoms makes the calixarenes selective for heavy metals rather than the alkali cations that are usually the primary ions for calixarene-based ISEs.

5.2.1.2 Lead The lead electrode is useful for monitoring aqueous concentrations of Pb^{2+}. Provided that the sample pH is between approximately 4 and 7, the linear range typically extends from 10^{-1} to 10^{-6} M with a DL of 10^{-7} M being observed. Under basic conditions, the LOD is restricted because of the formation of metal hydroxides. At lower pH values, the lead and silver sulfides used to form the sensing element become more soluble causing the LOD to increase. The ability of the ISE to discriminate against alkali and alkaline earth metals is good, but Cu^{2+} and Fe^{3+} represent significant interferences. High concentrations of chloride may also cause difficulties in accurately monitoring lead levels. In practical use, the surface of the electrode tends to become oxidized, and mechanical or electrochemical repolishing is required periodically. The lead electrode has also been quite widely used for the indirect determination of sulfate.

5.2.1.3 Copper Copper-sensitive ISEs can be formed by co-precipitation of copper and silver sulfides that are then pressed and sintered to form disks. Alternatively, the precipitate can be dispersed within an inert binder.

The resulting sensing element contains an intimate mixture of the two sulfides and a ternary compound jalapite ($Ag_{1.5}Cu_{0.5}S$). Mercury(II), silver(I) and chloride interfere significantly in the copper determinations. In common with the lead and cadmium electrodes, the response of the copper ISE does not always give the predicted Nernst slope of approximately 30 mV dec^{-1} when complexes are present. The DL for free metal concentrations is impressive, at 10^{-10} M, but is rarely required in environmental analysis where divalent metal ion concentrations are normally above 10^{-7} M.

5.2.1.4 Alkali Metals Neutral-carrier-membrane ISEs, e.g. hydrophobic esters of phosphoric acid or *N*,*N*,*N*′,*N*′-tetracyclohexyl-3-oxapentanediamide (ETH 129), or functionalized calixarenes, immobilized within plasticized PVC, are the most important calcium sensors. Calcium ISEs typically exhibit Nernstian responses to Ca^{2+} activity in the range 10^{-1}–10^{-7} M in metal ion buffers. The observed potentials are usually independent of pH between 5.5 and 9. The majority of applications lie in the clinical domain, e.g. calcium levels in renal and muscle cells, as well as neurons, and the only environmental application of note is the determination of water hardness. The direct potentiometric method can be used to rapidly measure water hardness. However, an indirect potentiometric method involving ethylenediamine tetraacetic acid (EDTA) titration is preferred. Potassium ISEs based on immobilized valinomycin are very successful and have been used for potassium determination in ores, slags and coolants in water-cooled power reactors, and for monitoring fertilizer run-off from agricultural land.

5.2.2 Anions

5.2.2.1 Chloride ISEs are approved by the USEPA for the determination of simple chloride ions in drinking waters, natural surface waters, groundwaters, domestic and industrial wastewaters and in soil extracts.[53] The DL of the method is 2.0 ppm and chloride concentrations between 0.4 and 1000 ppm can be measured, although concentrations less than 2.0 ppm can be overestimated by approximately 60%. Measurements in solutions that contain high levels of iodide, cyanide or sulfide should be avoided since these anions form silver salts that are less soluble than silver chloride, which forms the basis of the sensor. Erroneous readings may also be obtained if the sensor is exposed to ammonia, because these solutions tend to dissolve silver chloride. Sulfide, cyanide and ammonia can be removed as interferences by acidifying the solution to pH 4 using sulfuric acid, while addition of acidified potassium bromate oxidizes the iodide and bromide and removes them as interferences. Other interferences arise from metal ions, e.g. Fe^{3+} and Al^{3+}, that complex chloride preventing it from being measured. Under these circumstances, the sample is usually treated with EDTA, which forms strong complexes with the metal ions.

5.2.2.2 Cyanide Cyanide in aqueous samples is an environmentally important analyte that can be quantified using a potentiometric sensor.[54] Using this approach, the free cyanide and hydrocyanic acid concentration can be measured, or the total cyanide level determined if the sample is first distilled. The DL is 0.05 ppm and cyanide concentrations from 0.01 to 10 ppm can be determined. However, results less than 0.05 ppm may be up to 120% too high. The main interferences arise from transition metal ions that form strong complexes with cyanide which cannot be measured by the ISE. Distillation decomposes the metal–analyte complexes allowing the total cyanide concentration to be determined. The method can be extended to the analysis of soil samples after a suitable extraction step.

5.2.2.3 Fluoride The first significant anion-selective ISE was the fluoride-selective electrode reported by Frant and Ross[55] in 1966. This sensor is especially important as there are not many alternative methods available for fluoride monitoring. The selectivity and overall performance of this sensor are impressive, with hydroxyl representing the only significant interference. The determination of fluoride levels in potable water is important since a level of 1 ppm fluoride is recommended to promote dental health. The fluoride ISE offers excellent performance, with a typical DL of 0.5 ppm and a linear range between 0.025 and 500 ppm being obtained. However, using a linear calibration procedure may result in samples with fluoride concentrations less than 0.5 ppm being read approximately 160% too high. As is the case for chloride, polyvalent metal ions represent a significant difficulty if the objective is to determine the total, rather than free, fluoride concentration. This problem can be reduced by adding a buffer to adjust the total ionic strength which contains a strong metal chelator. The sample pH is a critical issue since the selectivity coefficient for hydroxide is approximately 0.1. Therefore, the pH is usually adjusted to between 5 and 5.5. Too acidic a medium should be avoided because at low pH values fluoride forms HF_2^- which cannot be detected by the ISE.

There is a long history of using ISEs for industrial hygiene monitoring, especially through the determination of fluoride in urine.[56] A National Institute of Occupational Safety and Health (NIOSH) method for fluoride has been established using this analytical approach.[57] In keeping with the demands of the workplace, the method is uncomplicated and involves the simple dilution of a urine sample with buffer, and direct measurement of the fluoride activity using the ISE. The addition of the pH buffer

minimizes the impact of H_2O_2 and Ca^{2+}. The reported range of the method is approximately 0.20–2000 ppm of fluoride.

5.2.2.4 Sulfide ISEs can be used to determine the total sulfide concentration in aqueous samples. The method is applicable only to samples distilled from a scrubber solution that contains oxygen scavengers such as salicylic or ascorbic acid, because of possible interference from mercury and silver. Also, distillation decomposes sulfide complexes to free sulfide dianions that can be determined by the ISE. The calibration range is between approximately 0.1 and 12 000 ppm. Results obtained for solutions containing less than 1 ppm sulfide may be approximately 90% too low. Silver, mercury, humic acid or thiosulfate do not interfere significantly with the analysis.

Underground corrosion, spoilage of petrol, paper pulp and foodstuffs can be caused by anaerobic sulfate-reducing bacteria. Therefore, the detection of these bacteria is an important economic objective. The sulfide ISE is not only capable of determining sulfide concentrations at the parts per billion level, it can also detect the initial growth of sulfate-reducing bacteria.[58] Further studies demonstrated that sulfate, sulfite, thiosulfate, pyrosulfite and dithionite, but not dithionate, are converted stoichiometrically to sulfide by bacteria such as *Desulfovibrio desulfuricans*, *D. gigas* and *D. vulgaris*.[59] Sulfide ISEs have also been used to monitor sulfide and thiols in petroleum process streams.[60]

5.2.2.5 Nitrate The USEPA has deleted the brucine–sulfanilamide method for determining the solubilized nitrate concentration (method 9200) and replaced it by an ISE method.[61] The original approach has been abandoned because it produced unreliable results. The ISE method gives a LOD of 2.0 ppm and nitrate concentrations from 0.2 to 1000 ppm can be measured. It is important to note that simple linear calibration models can introduce significant errors at both the high and low ends of this range. For example, results obtained for samples containing <2 ppm nitrate may be up to 400% too high, while results for solutions containing >400 ppm nitrate may underestimate the nitrate concentration by approximately 50%. The nitrate ISE is prone to a number of interferences that are typically masked by adding appropriate reagents. For example, cyanide, bisulfide, bicarbonate, carbonate and phosphate are removed as interferences by adjusting the pH to 4 with boric acid. The halides are removed as precipitates by adding silver sulfate. Nitrite can be removed by adding sulfamic acid. As discussed in section 3.2, adding reagents will change the ionic strength of the sample, which may in turn change the activity of the target ion thus altering the ISE potential. Therefore, one must be careful that samples and calibration standards are treated similarly, or that an ionic-strength-adjusting buffer is used. Also, some prior knowledge of the interference concentration is desirable if the interferences are to be successfully eliminated. One must also be careful about contaminating the samples with chloride, e.g. from a leaking saturated calomel reference electrode, and the use of a mercury sulfate reference is recommended.

While the nitrate-selective electrode discriminates well between nitrate and chloride, $K^{pot}_{NO_3,Cl^-} = 4 \times 10^{-3}$, it is in fact more sensitive to perchlorate than nitrate, $K^{pot}_{NO_3,ClO_4} = 550$. Therefore, the nitrate ISE suffers from a strong interference from perchlorate. However, perchlorate is rarely present in samples where nitrate has to be determined. Despite the small value observed for $K^{pot}_{NO_3,Cl^-}$, the response of the nitrate electrode will be compromised where the chloride concentration is high. This difficulty has lead to the use of ''ion-buffers'' for sample pretreatment. In the case of a high background chloride concentration, silver sulfate is added to form a precipitate. Other ''buffers'' include the addition of aluminum sulfate to complex anions of organic acids, and the use of boric and sulphamic acid to decompose nitrite. When using these pretreatments, it is necessary to adjust the pH to approximately 3 by adding sulfuric acid so that any organic acids present remain undissociated and the hydrogen carbonate level is controlled.

5.2.2.6 Nitrite Nitrite levels within aqueous environmental samples can also be determined using an ISE.[62] The DL of the method is 0.05 ppm with a calibration range that extends from 0.05 to 20 ppm. In common with many anion determinations by ISE, when measuring nitrite levels a buffer that adjusts the sample pH and masks interferences must be added. Table 6 summarizes the selectivity coefficients observed for major interferences of the method.

5.2.3 Miscellaneous Species

5.2.3.1 Ammonia The gas-sensing ammonia electrode, the ammonium-sensitive liquid-membrane electrode and the ammonium-sensitive glass electrode can be used for determining ammonia in water. The liquid-membrane electrode has been used to monitor ammonia levels in natural bodies of water and boiler water feeds. However, it suffers from significant interference from alkali metal cations and has a higher DL than the gas-sensing ISE. In general, the poor selectivity of these ISEs makes them suitable only for application in high-purity waters.

5.2.3.2 Organic Amines Beyond the ability of functionalized calixarenes to sequester alkali and heavy

Table 6 Nitrite electrode selectivity data

Interfering ion	Log K_{ij}^{pot}	10% error ratio (ppm)
Hydroxide	2.8	–
Fluoride	−3.1	170
Chloride	−3.1	320
Chlorate	−3.4	1600
Perchlorate	−3.1	830
Bromide	−3.0	570
Iodide	−1.2	15
Sulfate	−4.1	1100
Nitrate	−3.3	200
Phosphate	−4.0	9500
Polyphosphate	−4.4	3400
Bicarbonate	−3.3	870
Acetate	−3.2	720
Lactate	−4.9	Unlikely to interfere
Phtalate	−2.5	380
Ascorbate	−4.2	Unlikely to interfere
Salicyclate	−0.8	7.0

metals, they are also able to complex organic cations. The best responses are obtained for primary amines with no substituents adjacent to the amino group, e.g. 1-octylamine, dopamine and hexamine. It appears that the host–guest interaction involves hydrogen bonding between the carbonyl groups of the calix[6]arene and the protonated amino group of the organic amine. Locating the alkyl chain of the amine within the hydrophobic cavity of the calixarene further enhances the stability of the inclusion complex.

5.3 Arrays in Water Quality Monitoring

There are many ion-selective chemical sensors that can play useful roles in determining water quality. However, relatively few of these sensors can be used for the *direct* selective potentiometric measurements in naturally occurring bodies of water or waste effluents that contain large and widely varying concentrations of interferences. Indirect measurements can enhance the reliability and quality of the analytical information while extending the number of target analytes. However, sampling and sample pretreatment are often an integral part of these procedures. One of the most promising approaches to addressing the difficult issues of reliability, multiple analyte detection, minimum sample pretreatment, real-time monitoring, etc. is the use of sensor arrays of the type illustrated in Figure 12.[51]

A sensor array for the detection of Cu^{2+}, Pb^{2+}, Cd^{+}, Zn^{2+}, Fe^{3+}, H^{+}, and Cl^{-} has been developed.[63]

Figure 12 Schematic representation of a 50-electrode array. The expanded section shows that each electrode is independently addressable, allowing simultaneous detection of many environmentally relevant ions, correction for inter-electrode interferences, and subsequent speciation into major components. (Reproduced from Shatkin et al.[51] by permission of the American Chemical Society.)

Over thirty different sensor materials, mainly chalcogenide vitreous alloys, were considered. The vitreous materials exhibit good sensitivity towards their primary ion but respond significantly to the other analytes of interest. While such ''cross-selectivity'' would be detrimental to the performance of a single device, in a sensor array it enhances the quality of the analytical information available, allowing each sensor to provide a pseudo-independent determination of the concentration of each analyte. An important consideration when using ISEs for direct water-quality monitoring, is to consider the effects of changing temperature and pressure on the ISE response. In this regard, ISEs fabricated using incompressible solid-state materials offer improved performance and outputs that are much less sensitive to the external pressure. For example, as illustrated in Figure 13, the observed potential for a chloride-selective ISE based on a crystalline membrane of $AgCl-Ag_2S$ varies linearly with concentration over three decades of concentration even when operated with an external pressure of 10 bar.

5.4 Soil Monitoring

Metals, notably the heavy metals, can be extremely toxic and unlike hazardous organic materials cannot be broken down in the environment. Therefore, there is a strong need for simple sensors capable of providing analytical, time- and distance-dependent information about metal concentrations in soil for both protection and cleanup purposes. However, all soils contain trace levels of metal and their presence is not indicative of contamination. Moreover, while Table 7 provides information regarding the content of various metal and metal-like elements in soil,[64] local variations can be rather dramatic. For example, the average concentration of 0.3 ppm for Se can naturally reach 1200 ppm in seleniferous soils.

Figure 13 Chloride-selective sensor response under the pressure and in the typical concentrations found in natural and seawater. (Reproduced from Legin et al.[63] by permission of Elsevier Science.)

Metals within soils can exist either within the soil solution or bound within the organic and inorganic components. The metals may be free (uncomplexed), e.g. Cd^{2+}, Cu^{2+}, Hg^{2+}, in various complexes, e.g. $CdSO_4$, $ZnCl^+$, AsO_4^{2-}, or exist in their elemental forms. Therefore, not only is total metal concentration of interest, it is highly desirable to know bound vs free concentrations and valence states.

Soil analysis using an ISE is typically performed by either investigating samples of soil solution, i.e. collecting water runoff within the soil, or by extracting the soil into an aqueous medium. After suitable cleanup, e.g. to remove waste organic matter and humic acid, these samples can then be analyzed using the same ISE-based methods described for water samples. Several of the metals listed in Table 7, e.g. copper, cadmium, silver and lead occur at concentrations that can be directly read using an ISE. Others, e.g. mercury, require either specialized sensors capable of ultralow-level determinations, or more usually a preconcentration step.

Beyond metal analysis, nitrate determination in solids is an important application of ISEs. Concern about the intensive application of nitrogen-based fertilizers, and their potentially adverse effects on the environment, has driven the development of improved fertilizer management. Different soil-nitrate levels within a single field mean that application levels ought to be adjusted across the field to provide the optimum nutrient level for the particular crop. Use of conventional sampling and analysis techniques is not practical in this instance because

Table 7 Typical content of various metals in soils

Metal	Selected average for soils (ppm)	Common range for soils (ppm)
Al	71 000	10 000–300 000
Fe	38 000	7000–550 000
Mn	600	20–30 000
Cu	30	2–100
Cr	100	1–1000
Cd	0.06	0.01–0.70
Zn	50	10–300
As	5	1–5
Se	0.3	0.1–2
Ni	40	5–500
Ag	0.05	0.01–5
Pb	10	2–200
Hg	0.03	0.01–0.3

of the cost and time required for intensive sampling. Real-time nitrate sensors make it feasible to locally map the nitrate levels within farmland, thus maximizing yields while minimizing cost and environmental impact.

5.5 Gaseous Environmental Pollutants

Gaseous pollutants represent one of the most formidable threats to the environment because they possess a unique ability to travel considerable and often unpredictable distances. Furthermore, substances not commonly regarded as gases may also be released into the atmosphere as aerosols, including heavy metals such as lead. Such releases represent an immediate threat through inhalation. Moreover, they can be rapidly deposited, e.g. absorbed by soil, water or plant-life. Gaseous chemicals can be incorporated into rain, e.g. dissolution of NO_2 and SO_2 results in destructive acid rain. Table 8 shows the more important gaseous atmospheric pollutants that can be analyzed by ISEs. The majority of gaseous tropospheric pollutants are produced as a consequence of combustion and volcanic activities.

Air monitoring presents some unique problems to the analyst as a result of the gaseous state of the analyte. Continuous monitoring is often required, making spectroscopic approaches particularly attractive. Although some ISEs are capable of performing in situ determinations of analyte concentrations in gaseous samples, the majority of ISE-based determinations involve aqueous samples. Thus, ISE-based analysis of gases is typically a batch process in which the sample is adsorbed within a solid or liquid matrix and subsequently analyzed as an aqueous sample.

Table 8 Gaseous analytes and sources that are amenable to determination by ISE

Compound	Biogenic sources	Anthropogenic sources
CO_2		Oxidation most commonly from combustion of hydrocarbon materials
NO	Soil biochemistry, electric storms, natural fires	Combustion of oil, gas and coal
NO_2	Soil biochemistry, electric storms, natural fires	Combustion of oil, gas and coal
NH_3	Aerobic decomposition of biological material in the soil	Coal and fuel oil combustion, waste treatment, agriculture
SO_2	Volcanic activity, oceans and swamp emissions	Nonferrous metallurgical extraction, combustion of oil and coal
H_2S	Volcanic activity, anaerobic fermentation	Oil refining, farming, polymer and paper industry
HF	Volcanic activity	

Wet collection systems, usually involving buffered aqueous solutions, are employed to extract the analyte from the gaseous sample. Combinations of bubblers and diffusers provide efficient air-to-absorbant contact. This method offers certain advantages, e.g. since the samples are preconcentrated, very low DLs can be achieved in comparison to direct-reading methods. However, the ability to absorb a target analyte may be limited by the low solubility of the particular gas in aqueous media or by slow diffusion across the gas-permeable membrane, which leads to slow response times and poor selectivity.

5.5.1 Carbon Dioxide

This greenhouse gas is produced ubiquitously during combustion processes. Monitoring of CO_2 emissions is important for understanding its role as a greenhouse gas, for detecting rain-forest destruction, and for controlling biotechnological activities. Many very effective Severinghaus-type gas-permeable membrane electrodes are commercially available for measurement of CO_2, and ISEs are the method of choice for carbon dioxide monitoring.

These sensors can determine CO_2 levels either in solution or in humidified air. The probe uses glass and reference electrodes mounted behind a gas-permeable membrane such as silicone rubber. A thin film of aqueous sodium hydrogen carbonate solution separates the membrane and the surface of the glass electrode. Sample CO_2 gas traverses the permeable membrane until the partial pressures of CO_2 in the sample and in the internal filling solution are equal. CO_2 reacts with the $NaHCO_3$ internal filling solution to form carbonic acid. The glass electrode monitors the pH of the filling solution and the magnitude of the pH shift can be used to indirectly determine the CO_2 concentration. Buffering of samples and standards below pH 4.5 is often required to ensure conversion of carbonate and bicarbonate to CO_2. Because CO_2 diffuses rapidly out of acidic solution, it is important to minimize the surface area of the sample, to avoid vigorous stirring and to make measurements as soon as possible after acidification.[65]

The LOD is rather low, with a limit of 1×10^{-5} M being observed for most electrodes. Depending on the membrane employed, this method may be prone to interferences. Microporous membranes provide little selectivity and are particularly prone to permeation of water vapor, which may swamp the electrode and produce significant drift. The most important interferences are

volatile gaseous species such as SO_2 and NH_3. While silicone rubber offers good selectivity and a high diffusion coefficient for CO_2, it is prone to interference from the passage of organic acids which may change the pH of the detector.

5.5.2 Nitrogen Oxides

NO is liberated as a product of many combustion processes but is oxidized by ambient air into NO_2. This is an extremely toxic gas at high levels and an irritant at low levels, and is a primary component of photochemical smog. The NO_x level in air usually varies from 1 to over $100\,\mu g\,m^{-3}$. Therefore, it is an important target analyte in environmental monitoring. An ISE using a chalcogenide glass ($Se_{60}Ge_{28}Sb_{12}$) as the sensing element can selectively determine NO_2 without interference from nitric oxide, sulfur dioxide, carbon monoxide, methane and other gases. However, a number of other approaches to the potentiometric analysis of NO_x have been taken. The traditional nitrogen oxide electrode arrangement is analogous to the Severinghaus-type gas sensor described in section 4.3. This electrode responds to dissolved nitrite or nitrous acid. In air-quality monitoring applications, the gaseous NO_2 is collected in an appropriate collection medium where it is hydrolyzed to acidic nitrite which is then detected by the glass electrode. Unlike the CO_2 electrode, the inner filling solution is unbuffered, but maintains a high nitrite concentration. The dissolved NO and NO_2, which are in equilibrium with the HNO_2 in the acidified sample, diffuse across the electrode membrane and establish an equilibrium between NO_2^- in the sample and electrode thin film.[66]

As with all Severinghaus electrodes, interference arises from the nonselectivity of the membrane to other pH-altering species. To address the problem of ISE selectivity, Meyerhoff[67] replaced the glass pH electrode detector with a polymer-membrane electrode coupled to a membrane dialyzer injection loop. The NO_x was pumped through a Teflon® membrane and trapped in an oxidizing recipient solution where it was converted to nitrite, which was then detected by the polymer-membrane electrode. This system enhanced the selectivity of NO_x detection and was semiautomated for continuous flow. Modifying the gas-permeable membrane may also be productive, e.g. the selectivity and sensitivity of nitrite sensors is enhanced by incorporating cobalt(III)cobrinate into microporous PVC membranes.[68,69]

Nitrogen oxides can be chemisorbed on lead dioxide heated to 190 °C to form lead nitrate which, after extraction, can be measured using a nitrate ISE. Carbon dioxide, water vapor and nitrogen do not absorb and therefore do not interfere with the measurement. However, when the sulfur dioxide concentration is more than ten times the nitrogen oxide concentration, positive errors will be observed. Nitrogen oxides can also be selectively oxidized by passing them through a 2% hydrogen peroxide solution for 24 h at a rate of $2\,L\,min^{-1}$. Unreacted peroxide is then removed by adding manganese dioxide and the nitrate level is quantified using a nitrate ISE. Unlike the lead dioxide method, even a forty-fold excess of sulfur dioxide does not interfere with the analysis.

One of the great advantages of ISEs is that their small size and portability lends itself to in situ monitoring. A personal dosimeter that first oxidizes NO to NO_2 using sodium dichromate and sulfuric acid on a glass filter, followed by further oxidation using peroxide and determination of the resulting nitrate, has been developed.

5.5.3 Sulfur Dioxide

Sulfur dioxide is an important component of air pollution and its production by power-station smokestacks is routinely monitored. The major global contribution to SO_2 comes from natural volcanic activity, and the anthropogenic contributions are produced in the metallurgical extraction industry and from the burning of high-sulfur coal. When in the troposphere, this gas actively participates in physicochemical processes such as cloud and aerosol formation, making it the major contributor to acid rain. The atmospheric concentration of SO_2 varies very significantly and can reach $5\,mg\,m^{-3}$ in heavily polluted air.

Atmospheric monitoring of SO_2 is generally carried out using batch analysis, because preconcentration is required owing to the insensitivity of most analytical methods. Preconcentration is typically achieved by bubbling the gaseous sample through a buffered solution of tetrachloromercurate(II) whose pH is maintained at a value of 6.9 to ensure quantitative adsorption. The adsorption process results in the formation of $Hg(SO_3)_2^{2-}$. After chemical removal of interfering nitrite (by addition of amidosulfonic acid), the solution is acidified to release the sulfur dioxide gas. A number of more selective electrodes have been reported, for example Meyerhoff et al. have detected SO_2 after reduction by a sulfite-selective polymeric membrane electrode based on bis(diethyldithiocarbamato) mercury(II).[70–72]

5.5.4 Ammonia

Ammonia plays an active role in atmospheric pollution chemistry. It is thought to contribute substantially to atmospheric NO_x and, as the only basic trace gas constituent of the atmosphere, it plays an important role in the chemistry of the acidic gases NO_2 and SO_2. Concentrations of NH_4^+ and NH_3 in the unpolluted

atmosphere do not exceed a few micrograms per cubic meter. Therefore, sensors with low LODs or preconcentration are required.

The Severinghaus-type ammonia gas sensor is one of the more effective ISEs available for atmospheric monitoring. It responds very selectively to dissolved ammonia and, with the exception of volatile amines, is subject to very few interferences. Use of a PVC–nonactin composite membrane[73] is reported to improve the analytical performance with semiquantitative detection of ammonia gas in the range 260–0.4 ppb being achieved. In the more common batch technique, gaseous ammonia is collected in an absorbing medium either directly or after adsorption onto a solid support.[74]

5.5.5 Halides in Air

The solid-state fluoride-selective electrode is one of the earliest examples of the application of ISEs to atmospheric monitoring.[75,76] Sampled air is usually passed through a collection medium and monitored by either a solid fluoride ISE or a HF gas-sensing probe. Chlorine is most commonly measured using the chlorine gas-sensitive probe, where the sensing probe is either acid- or chloride-sensitive. Airborne halide-containing acids, e.g. hydrochloric and hydrobromic acids, which ionize to yield free halide ions, both pose health risks and cause corrosion problems. In common with the analysis of metal particles in air, the halide analyte is first trapped on an impregnated filter through which a known volume of air is drawn. Cellulose acetate is commonly used as a sorbent for both particulate and gaseous halides. The halide species is extracted or wet-ashed in alkaline solution, diluted appropriately and analyzed by ISE. By using a filter to preconcentrate the analyte, the poor LODs associated with these ISEs can be circumvented and trace levels can be measured successfully.

5.5.6 Heavy Metals in Air

Typically, to perform a potentiometric determination of heavy metals that may be present in air, particulate material is first collected using a filter with a sufficiently small pore size to trap the material. A given volume of air is drawn through the filter at a predetermined rate and then the filter is digested, typically in acid. Following suitable neutralization and dilution, the filter contents are analyzed. This approach has been used to determine the concentration of mercury in air.[77] While voltammetry is often the preferred electroanalytical technique because of its lower LODs and multianalyte capabilities, potentiometry avoids the high background signal of adsorptive stripping voltammetry due to intermetallic effects and double layer charging when attempting to determine mercury levels. The potentiometric analysis of mercury within gas samples taken from flue exhausts compares favorably with results obtained using cold-vapor AAS.[77]

6 CONCLUSIONS AND FUTURE DIRECTIONS

A significant range of environmentally important analytes can now be determined using simple and inexpensive ISEs. The range of accessible analytes will undoubtedly continue to grow as synthetic and materials chemists devise ever more robust and selective membranes. Recent developments in ISEs, including sensor arrays, miniaturized devices, portable instrumentation and advanced ISFETs, have not yet been widely exploited in environmental monitoring. Indeed, compared with other analytical methods such as spectroscopy and chromatography, electroanalytical methods in general (and ISEs in particular), have been somewhat under-utilized. In the past, ISEs have suffered from problems of mechanical ruggedness, interferences and long-term stability. However, these difficulties have largely been solved for many analytes allowing for more routine application.

Improving the recognition chemistry is pivotal to ISEs making further contributions in the area of environmental monitoring. Research will continue to refine the selectivity using existing approaches, e.g. the ability to tune ionophore selectivity by both the nature of the substituents and the conformation of the host will continue to increase the range of target analytes. These synthetic efforts will benefit from increasingly sophisticated molecular modeling that will reduce the synthetic cycle time and increase the likelihood that highly selective ionophores will be produced. New transduction mechanisms will be exploited, e.g. phase changes, and combined detection mechanisms, e.g. optical and electrochemical signals, will be developed. Successful ISE-based environmental monitoring must be interdisciplinary and demands that instrumentation specialists, surface scientists, mathematicians, theoretical chemists and materials chemists form strategic alliances. New materials, in particular those with attractive properties (e.g. easily processed, good physical and chemical stability) for applications ranging from encapsulating materials to solid-state reference electrodes will play important future roles.

''Intelligent sensing systems'' capable of recognizing and responding to changes in the concentration of environmental pollutants in a dynamic manner are likely to be an important future development. Smart sensors incorporate electronic logic, control and processing functions to offer enhanced measurement capabilities, information quality and functional performance. While these features are currently predominately found in

silicon-based transducers, they are appearing in ISEs, e.g. on-line temperature compensation.

From a fabrication perspective, the major research drive is to fabricate sensors using planar technologies. Therefore, there is intense interest in developing thin and thick films suitable for chemical sensing. Self-assembly, spontaneous adsorption, Langmuir–Blodgett and chemical vapor deposition (CVD) are all being used to produce films whose structure and chemical composition is carefully controlled and optimized for the detection of specific analytes. Miniaturization will be a recurring theme. In particular, potentiometric sensing in solids, nonpolar solvents, supercritical fluids and gases, will greatly diversify the range of environmental media in which ISEs can be successfully applied.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectroscopy
AES	Auger Electron Spectroscopy

Soon after the invention of the laser by Maiman, laser pulses were used for excitation and ionization of sample material for inorganic analysis by optical emission spectrometry (OES) or mass spectrometry (MS). This direct approach is complicated by the complexity of the laser–sample interaction and the need to optimize simultaneously the sampling and excitation (or ionization) steps. Use of a laser for solids sampling with separate atomization and excitation in an inductively coupled plasma (ICP) retains the advantages of direct solids analysis, including spatially resolved concentration data, and adds those attributable to the ICP, including wide elemental coverage, a linear dynamic range of six or more orders of magnitude, and excellent detection limits (DLs). The resulting techniques, denominated laser ablation/inductively coupled plasma/optical emission spectrometry (LA/ICP/OES) and laser ablation/inductively coupled plasma/mass spectrometry (LA/ICP/MS), are based on recording of relative emission intensities or ion count rates, respectively. Both methods are treated here, but emphasis is given to LA/ICP/MS, a rapidly developing technique in use for less than 15 years, which in addition to offering DLs typically 10^3 times lower than those obtained by LA/ICP/OES, also offers isotope ratio analysis. Hardware, analytical procedures, performance, and prospects are addressed. The power and limitations of the methods are illustrated by environmental applications, including the analysis of metals, soils, rocks, and plastics.

1 INTRODUCTION

The ICP has been used for a quarter of a century as a source for atomic emission spectrometry (AES), in which detection of element-specific optical emissions is used to determine analyte concentrations in aqueous sample solutions. The advantages of inductively coupled plasma/atomic emission spectrometry (ICP/AES) or inductively coupled plasma/optical emission spectrometry (ICP/OES), include multielemental analysis, rapid sample throughput, low noise, low background, freedom from interferences, and DLs down to the sub ng mL^{-1} range.[1]

However, ever greater analytical performance required for new applications in biomedical, geological, and environmental science led, in the mid 1970s, to searches for yet more powerful analytical instrumentation. One idea for a novel analytical technique was to marry the advantages of the ICP as an ion source with the convenience and sensitivity of MS. The resulting technique, now known as inductively coupled plasma/mass spectrometry (ICP/MS), was developed by research groups in Britain, Canada, and the USA.[2] Advantages of the union of the ICP ion source and the quadrupole mass spectrometer include rapid multielemental analysis, high sample throughput (up to about 70 samples per day), typical DLs in the pg mL^{-1} range, calibration against simple aqueous standards, a linear dynamic range of seven or more orders of magnitude, relatively simple spectra, and an intrinsic isotope ratio analysis capability.[3]

Samples for ICP/MS analysis are introduced as an aerosol into the central channel of a torch consisting of several concentric quartz tubes. The plasma is maintained by radio-frequency power (typically about 1.3 kW) fed to a load coil near the mouth of the torch through which argon is fed. The resulting fireball is an almost perfect environment for the desolvation, volatilization, dissociation, and ionization of the sample.

Principally singly charged cations are produced, which are extracted from the plasma at atmospheric pressure by an ingeniously designed interface directly into the low-pressure analyzer of the spectrometer.

Both ICP/OES and ICP/MS, today used worldwide for elemental analysis, are dealt with in this article. More specifically, one form of sample introduction is addressed: laser ablation (LA). However, far greater emphasis is given to LA/ICP/MS since this method is younger, developing more rapidly, and offers more prospects for innovation than LA/ICP/OES. Henceforward, therefore, LA/ICP/MS is addressed but much of the commentary also applies to LA/ICP/OES.

Samples for analysis by either of the ICP methods are usually put into aqueous solution and dispersed into fine droplets. The droplets are traditionally produced by a pneumatic or an ultrasonic nebulizer, which discharges into a spray chamber. This method is extremely successful, allowing straightforward calibration against aqueous standards and the use of internal standards to correct for any drift in instrument sensitivity. However, the defects of nebulization include temporal variation in the particle size distribution; the adhesion of certain elements, such as iodine, to the inner walls of the glass spray chamber and their later release during analysis (so-called memory effects); and low efficiency, especially for pneumatic nebulization, where around 98% of the sample solution is lost to the drain. Moreover, sample dissolution often requires lengthy (half a day or more) digestions, frequently employing potentially hazardous reagents such as hydrofluoric acid. Analytically too, dissolution introduces the possibility of the loss of volatile elements, contamination from glassware, and the unavoidable introduction of constituent elements of the reagents used, which can, in ICP/MS, produce spectral interferences in the sample analysis. For example, when hydrochloric acid is used as the solvent the species $^{40}Ar^{35}Cl^{+}$ may be produced in the plasma and be preserved in the mass spectrometer, leading to unrepresentative intensities at a mass to charge ratio (m/z) of 75, where arsenic is determined.

Partly in response to such difficulties, many alternative sample introduction strategies previously used with ICP/OES have been coupled to ICP/MS over the last decade. Rapid sample heating is the basis of some of these methods, specifically of electrothermal vaporization (ETV), spark ablation (SA), and LA. In ETV the sample is placed on a graphite rod and subjected to a rapid temperature ramp, resulting in vaporization of the sample into a carrier gas stream (usually argon) which transports it to the plasma. Similarly, in SA surface material is removed by the action of a high voltage spark. Advantages of ETV and SA include the ability to work with microliter sample volumes and direct solids analysis, respectively.

One of the most versatile methods of sample introduction is the use of laser pulses to mobilize sample material directly from the solid and, as with ETV or SA, entrain it in a carrier gas flow for transport to the ICP. Advantages of LA/ICP/MS encompass:

- independent optimization of the ablation and spectrometer parameters;
- little or no sample preparation;
- high sample throughput;
- very rapid semiquantitative analysis;
- reduced spectral interferences;
- spatially resolved analysis.

In the following sections the main features of the lasers used, LA systems, and laser–solid interactions are outlined. Some alternative analysis procedures are described. Specific illustrative applications of the technique to elemental environmental analysis are then given. Isotope ratio analysis is addressed separately. An overview of the analytical performance and current status of the method follows. Finally, prospects for development are assessed.

2 LASER ABLATION SYSTEMS

2.1 Laser Principles

Following the introduction of the first coherent source of microwave radiation, the maser, in 1953, attention turned to the possibility of producing a coherent visible light source – the laser (an acronym for light amplification by stimulated emission of radiation). This was achieved in 1960 by Maiman[4] of the Hughes Research Laboratory using a ruby crystal as the active medium. A typical ruby

Figure 1 Ruby laser with a straight flashlamp in an elliptical cylinder configuration. (Reproduced by permission of John Wiley & Sons Inc., from B.A. Lengyel, *Lasers*, © Wiley-Interscience, p. 106 (1971).)

laser is shown in Figure 1. The elliptical reflector encloses a ruby rod and flash tube. The end surfaces of the ruby are highly polished and silvered, one end fully the other partially. The latter allows pulses of light to escape when lasing occurs. (Alternatively, mirrors external to the ruby may be used.)

Ruby consists of aluminum oxide, Al_2O_3, to which has been added a small proportion (about 0.05% by weight) of Cr_2O_3. The chromium, in the form Cr^{3+}, provides the energy levels between which stimulated emission is triggered. Chromium ions in the ground state are excited to an upper energy band by an intense flash of white light from the flash tube in a process known as optical pumping. A spontaneous non-radiative transition (phonon relaxation) to a lower metastable level then occurs. As a metastable state has a relatively long lifetime, its population can be increased at the expense of that of the ground state, producing a population inversion.

Spontaneous transitions emit photons which trigger further emissions. The photons traveling perpendicular to the ends of the ruby rod build up in the resonator and are released from the partially silvered ruby face. Once started, stimulated emission depopulates the upper lasing level much faster than the pumping rate of the flash tube. Consequently, in this free-running or normal (N) mode, the light output consists of many intense spikes. Pulse widths from about 0.1 to 1 ms are typical. However, it is possible to control the output of a laser by building up such a high population inversion through use of a light seal on the active medium that when it is opened a giant pulse is produced. The quality (Q) factor of a resonator is a measure of the net energy stored. Thus rapid modification of the Q factor, by use of a shutter for example, is the key to the method known as Q-switching. The pulses so produced, known as Q-switched or Q mode pulses, have typical durations in the range 0–1000 ns. Figure 2 shows schematically the principles of production and the form of free-running and Q-switched pulses.

Figure 2 Schematic of a ruby laser with a high-speed shutter for Q-switching. The temporal forms of N and Q mode pulses are also shown.

Figure 3 Energy-level diagram for Nd : YAG, indicating the optical pumping and laser transitions. (Reproduced by permission of Elsevier Science from Moenke-Blankenberg, 'Laser Micro Analysis', *Prog. Analyt. Spectrosc.*, **9**, 335–427 (1986).)

The ruby laser is of some interest since it was the first used to ablate solids for introduction to ICP/MS.[5] Subsequently, neodymium:yttrium aluminum garnet (Nd : YAG) lasers[6] have mainly been used. The energy level system of Nd : YAG is shown schematically in Figure 3. The lasing transition is between levels E_1 and E_3. As the population of E_3 is very low at room temperature, relatively little optical pumping power is required to produce a population inversion compared to a ruby system.

2.2 Laser Ablation Inductively Coupled Plasma Mass Spectrometry Hardware

A typical LA system[7] is shown in Figure 4. The laser may be mounted as shown or in the horizontal plane, the beam being reflected onto the sample through 90° by a

Figure 4 Laser, ablation cell, and associated gas lines. (Reproduced by permission of the Japan Society for Analytical Chemistry from Mochizuki et al.[7])

mirror. Samples are placed on a stage within a glass (or quartz) cell. The stage can be moved in the x, y, and z directions by a stepper-motor under computer control. The size and direction of the steps is controllable, and the laser is synchronized to fire only when the sample is at rest. A pre-selected number of laser shots are fired onto the sample surface, where rapid local heating causes the eruption of material in the form of molten droplets and vapor. Spectrometer data acquisition may be triggered by the first laser shot or after a pre-set delay. The sample surface may be viewed either by eye through a microscope equipped with a suitable protective filter or remotely via a video camera. Traditionally, visual and laser focusing are arranged to coincide.

A gas flow, usually of argon, is fed to the ablation cell via a precision flowmeter and entrains some of the ablated material, which is thus transported to the ICP. The cell is easily accessible for rapid sample exchange. However, as air must not be admitted to the ICP, a by-pass valve is installed beyond the cell exit line to provide an uninterrupted flow of argon and to allow purging of the cell to atmosphere.

2.3 Laser–Solid Interactions

Owing to the complexity of the process and the large number of physical variables to be considered, the influence of the incidence of a laser pulse on a solid surface cannot be analyzed as a single problem. We may say that a portion of the incident light is absorbed to a depth of a few microns. Laser photons are absorbed by electrons in the conduction band of the material and energy is given up by collisions with other electrons and lattice phonons. As the time between collisions is much less than the shortest laser pulse, the absorbed laser energy is effectively transferred instantaneously to the solid as heat.

The rapid transfer of heat even from N mode laser pulses is enough to melt, or boil, many matrices, and material erupts from the region of impact at high velocity, forming a crater. This complex process is shown schematically in Figure 5(a) and (b). To illustrate further, scanning electron micrographs[8] of a pit produced in nickel by a pulse from a ruby laser are shown in Figure 6(a) and (b). The crater's edge is very well defined and the pit is roughly conical. Shots of higher energy produce larger craters with a wide region of melted material near the crater mouth. Q mode pulses of similar energy produce only a shallow surface melting.

To simplify our discussion two regimes: low and high irradiances, corresponding to irradiances of $<10^8\,\mathrm{W\,cm^{-2}}$ and $>10^9\,\mathrm{W\,cm^{-2}}$ may be distinguished. Very crudely these correspond to N and Q mode pulses, respectively. In the former regime, most of the material is removed as liquid, i.e. in the form of droplets. In the high irradiance regime much more vapor is produced. The gas above the sample is ionized and a plasma is formed, which in turn absorbs some of the incoming radiation and partially shields the sample surface. The complexity of the interaction is illustrated by the formation of a plasma even with N mode pulses, and this may in fact occur. As material erupts from the sample in the form of a plume, complex interactions occur between it, the plasma, and the incoming laser light.

Figure 5 (a) Laser–solid interactions. (b) Cross-section of an ablated crater in a solid. (Reproduced by permission of Elsevier Science from K. Dittrich, R. Wennrich, *Prog. Anal. Spectrosc.*, **7**, 139–198 (1984).)

Figure 6 The effect of the impact of a 0.3-J N-mode shot from a ruby laser. (a) Crater produced in a nickel disc. (b) Cross-section of an ablated crater. Ablated mass ≅ 120 μg. (Reproduced from Durrant.[8])

Although it is always prudent to have an understanding of the underlying physics and chemistry of the ablation process as a foundation for the development of analytical laser techniques, the interactions are so complex and dependent on so many laser and sample parameters that specific experimentation is always needed. Readers interested in pursuing the subject matter of this section will find an excellent start with the review by Moenke-Blankenburg.[9]

3 ANALYSIS PROCEDURES

LA/ICP/MS can provide an elemental analysis of the bulk of a sample, or some spatially-resolved data. Small spot sizes are required for the latter but not for the former. For the present, bulk analysis is treated, spatially-resolved or laser microprobe (LM) analysis being dealt with later (section 4.2).

3.1 Sample Preparation

One of the great advantages of LA is simply that samples do not have to be put into solution. Examples of preparation include selection of a fragment that fits within the ablation cell; mounting a piece in epoxy, cutting to expose a fresh surface, polishing and cleaning in methanol; pressing a powder, with or without a binder, into a pellet; production of a glass fusion. Even such limited sample preparation can bring associated problems such as contamination produced by ball-milling; or insufficient mixing with a binder, producing a heterogeneous sample. Any use of a binder also inevitably dilutes the sample. Weak laser to sample-surface coupling, e.g. between pulses from a ruby laser and pressed milk powder, may sometimes be increased by mixing the sample with a binder that shows greater absorption at the laser wavelength being used.

3.2 Optimization

The newcomer to LA/ICP/MS is faced with a bewildering array of parameters to optimize for quantitative elemental analysis. These relate to the laser, the sample, and the spectrometer. The outcome of the laser–solid interactions depends upon, among others, the wavelength, energy, mode, focusing, and angle of incidence of the laser beam. Wavelengths of 694 nm [ruby], 1064 nm, 532 nm (frequency doubled), 266 nm (frequency quadrupled) [Nd : YAG], and 193 nm [F excimer] have been employed, with the historical trend towards shorter wavelengths, i.e. from infrared (IR) to ultraviolet (UV), for more precisely controlled LA. Generally, however, the light wavelength is determined by the laser hardware and is therefore fixed for any specific laboratory system. Greater laser energies generally produce greater ablated mass and therefore greater responses. Laser shot energies may be varied by the use of beam filters or masks.

As already noted, the ablation process is strongly influenced by the use of N or Q mode pulses. The latter vapor-producing pulses should theoretically produce less fractionation, i.e. the selective removal from the sample of one element relative to another. However, such pulses, being extremely intense and rapid, sometimes produce memory effects by vaporization or re-suspension of material previously deposited in the ablation cell and transport tubing. Moreover, Q mode pulses are associated with an acoustic shock which is transported to the ICP, decreasing the reproducibility of the analytical signal. Such deleterious effects may be partially offset by the use of multiple low-energy (mJ) pulses at high repetition rates, e.g. 10 Hz, and such schemes have been practicable since the introduction of Nd : YAG lasers.

Focusing of the laser beam is an obvious parameter of interest. Both surface- and off-surface focusing have

been employed: the former to increase ablated mass and spatial resolution; the latter to deliberately reduce these for particular applications.

The angle of incidence of the laser beam will influence the complex plasma shielding produced above the sample. Thus instead of normal incidence an angle between the beam and the sample surface of 45° is sometimes employed.[6]

Unfortunately, the ablation process depends not only on the laser parameters but also on the nature of the sample – its color, reflectivity, thermal conductivity, mineralization, and so on. Indeed, it is just such dependencies that form the Achilles' Heel of fully quantitative analysis by LA/ICP-spectrometries. For our purposes one example of the difficulties involved in quantitation will suffice. Figure 7 shows the size distribution of droplets produced by ablation of stainless steel. Only droplets of a few microns in diameter will be transported to the ICP. Therefore, a shift in the size distribution, for example between ablation of a sample and a standard, will directly influence sample transport and hence the count rate measured by the spectrometer, leading to errors in quantitation.

Finally, the spectrometer parameters should be optimized. To maximize elemental responses the cell flow and ion lens voltages may be systematically varied while monitoring the $^{12}C^+$ signal, which appears to be due to the presence of CO_2 in the Ar flow. This procedure is simple but truly optimal performance is ensured only by using realistic conditions, such as the continuous ablation of a solid of known composition. A subtle complication is that varying the cell flow alters scavenging as well as the optimal sampling depth (torch to sampling cone separation), so that the latter should also be systematically studied.

Figure 7 Particle size and mass distributions of material produced by ablation of stainless steel by lightly Q-switched pulses from a ruby laser. The black bars represent the number of particles and the open bars the relative mass. (Reproduced by permission of The Royal Society of Chemistry from S. Chenery, M. Thompson, K. Timmins, *Anal. Proc.*, **25**, 68–69 (1988).)

Owing to considerations such as these, extensive systematic studies are very time-consuming, though some have been reported.[8,10] The requirement for multielemental analysis is sufficient sensitivity for the determination of the proposed analytes and the best practicable reproducibility. Higher laser energies ablate more sample and so give higher count rates, but excess ablation leads to the deposition of excess material in the cell and exit line, often leading to memory effects. Also, excess ablation will first cause a saturation of the counts of individual matrix elements, which may not be seriously detrimental to the analysis. However, higher rates of sample ablation will cause plasma disequilibrium, disrupting the ionization process in the ICP and preventing quantitation. Thus a set of compromise conditions must be found.

3.3 Quantitation

We may note first that quadrupole spectrometers collect data at specific m/z values (peak hopping) or across a range or set of ranges of m/z (scanning). As continuous exposure to very high count rates may damage the detector, any permanently saturated peaks, such as that of $^{40}Ar^+$, are deliberately skipped.

Before specific calibration procedures are considered, brief mention is made of blanks and DLs. In solution nebulization/inductively coupled plasma/mass spectrometry (SN/ICP/MS) a blank spectrum obtained from an analysis of the solvent (typically 2% v/v HNO_3) is usually subtracted from any sample spectrum. The most rigorous procedure for LA/ICP/MS is to produce a blank spectrum by ablating an inert target such as poly(tetrafluoroethylene) (PTFE) since this exactly simulates the sample analysis. The DL, a measure of the minimum detectable concentration, is defined as 3SDs of the blank. Either this definition or, perhaps more realistically, the line equals background equivalent concentrations for a blank may be used in LA/ICP/MS.

A single laser pulse produces a transient response, typically of 20 to 30 s, depending on the cell flow rate. The peak height or area may be used for quantitative analysis, but this approach is generally inferior to the use of the more stable response generated by multiple pulses of low energy, which yields better analytical precisions. Typical responses from multiple laser pulses are shown in Figure 8. Multielemental analyses based on transient responses are also impeded because of the need for rapid scan rates from the quadrupole spectrometers.

Rapid survey analysis was always possible by LA/ICP/MS,[6] but to obtain precise and accurate elemental concentrations is the principal challenge to researchers in the field. A semiquantitative analysis requires a standard containing a few known concentrations. A response versus mass curve is then produced (using the sensitivities

Figure 8 Response of ^{25}Mg obtained by LA/ICP/MS by ablation of a nickel disc using 0.3-J N-mode pulses from a ruby laser at (a) 1 Hz; (b) 0.5 Hz; (c) 0.17 Hz. To avoid overlapping, the responses are offset in the *Y* direction. (Reproduced from Durrant.[8])

Figure 9 A response curve obtained by the ablation of NIST SRM 612 Glass using 80-mJ Q-mode pulses at 15 Hz. Elements measured: Si, Ti, Ni, Mo, Sr, La, Ce, Pb, Th, U. (Reproduced by permission of Springer-Verlag from J.L. Imbert, P. Telouk, *Mikrochim. Acta*, **110**, 151–160 (1993).)

from the known elements and correcting for isotopic abundance) as shown in Figure 9. This has the advantage of allowing determination of elements not certified in the standard, but usually at the expense of reduced accuracy.

Simple element-for-element calibration against the sensitivities of individual elements of known concentration in an external standard has been employed.[11] For better accuracy and precision the standard has to have a similar structure and composition, i.e. the sample and standard are matrix-matched. Alternatively, a full set of well-characterized external standards may be used to obtain plots of response versus concentration. All laser and spectrometer parameters are kept constant for analysis of the samples and standards. Obvious difficulties include the non-availability of suitable standards and the expense of extensive use of standard reference material for calibration. In addition, standards are often inadequately characterized: elements of interest have not been determined or only ''guidance'' concentrations are given, or elements are certified at extremely low concentrations which do not provide sufficient counts for useful calibrations. Artificial standards made, for example, by adding aqueous standard solutions to a suitable matrix, drying, mixing, and pressing into pellets are sometimes successfully employed.

Internal calibration using responses obtained from elements in the sample itself may be used, requiring an independent determination of the concentration of a few elements in the sample.

Other approaches include external calibration on sensitivities obtained from the nebulization of standard aqueous solutions,[12] though this involves the loss of the advantage of working with a dry plasma, namely a reduction in spectral interferences. To overcome just such complications, internal standards[13] have recently been introduced to the outlet of an ablation cell by ETV. Similarly, Günther et al.[14] retained the advantages of calibration against solution samples by using a dual desolvation/LA system for the determination of rare earth elements (REEs) in soil, bestonite, and synthetic polyethylene, obtaining precisions of <10%.

Internal standardization is widely used in SN/ICP/MS to improve analytical precisions. In LA/ICP/MS its use is indispensable since differences in laser energy, surface texture, and so on, ensure that the ablated sample mass is not constant even for sequential analyzes. Normalizing the responses to that of a known element, usually a minor isotope of a major constituent, corrects for this type of variation. Between replicate internal standardization is easily performed because it does not require knowledge of the concentration of the element used. The procedure may be applied between the standard and the sample if the concentrations of an element are known in both.

4 APPLICATIONS IN ENVIRONMENTAL ELEMENTAL ANALYSIS

The specialty steels used in the construction of petroleum and petrochemical plants must be within the specifications for elemental composition if they are not to pose a safety hazard. Integrated electronics are now of such small dimensions that α-particle-induced damage is a serious problem, necessitating the use of aluminum wiring with U 7440-61-1 and Th 7440-29-1 impurities of $<1\,ng\,g^{-1}$. Knowledge of the concentration and distribution of elements in peridotites and their constituent minerals is essential to understanding the chemical evolution and composition of the lithospheric mantle. Such are

the challenges that LA/ICP/MS must meet. Illustrative applications are given below.

4.1 Metals

Metals are a logical starting point for study of the efficacy of LA/ICP/MS since they may be considered ''liquid solutions'' of uniform composition unless spatial resolution to the size of metal grains is considered. An example of the quantitative analysis of steels based on sensitivities obtained from a suite of steel standards is given in Table 1. As there are many characterized steels, this approach is more practicable than for other types of matrix. The sample was ablated using a 5×5 raster of points, covering a sample area of about $9\,mm^2$. Each crater was ablated five times with Q mode shots from a Nd : YAG laser at a repetition frequency of 4 Hz. Five such measurements were made per sample. Accuracies and precisions were typically $<10\%$ and DLs in the range $1-100\,\mu g\,g^{-1}$.

Additional examples of metals analysis are documented in Table 2.

4.2 Geological Materials

The difficulty of summarizing a large and rapidly growing literature is especially acute for geological applications. Several major themes, however, may be discerned: elemental analysis; fingerprinting; microprobe studies. Isotope ratio analysis, another active area, is dealt with separately in section 5.

Summaries of a number of studies of the determination of major, minor, and trace elements in matrices such as soils, silicates and carbonates are given in Table 3. Early studies using ruby lasers for ablation included the analysis of basalt[7] and Chinese reference soils.[11] A spectrum reproduced from the former shows the responses obtained for the REEs, Th and U (Figure 10). The peak integrals ranged from 150 to 4800 counts for the analyte isotopic concentrations of 0.16 to $5.8\,\mu g\,g^{-1}$. In the second study[11] the elements Na (7440-23-5), Mg (7439-95-4), Al (7429-90-5), Ca (7440-70-2), Sc (7440-20-2), Ti (7440-32-6), V (7440-32-6), Cr (7440-47-3), Mn (7439-96-5), Fe (7439-89-6), Co (7440-48-4), As , Rb (7440-17-7), Sb (7440-36-0), Cs (7440-46-2), Ba (7440-39-3), La (7439-91-0), Ce (7440-45-1), Nd (7440-00-8), Sm (7440-19-9), Eu (7440-53-1), Dy (7429-91-6), Ho (7440-60-0), Yb (7440-64-4), Hf , Ta , W , Th and U were determined in seven soils. Precisions were typically in the range 2–10% RSD, but some were considerably poorer for elements present at trace concentrations. DLs were as low as $0.1\,\mu g\,g^{-1}$ for many elements.

Often the objective of an analysis is identification of the source of the material and this does not require full quantitation. ''Fingerprinting'' of gold,[31] steel from safes, and glasses,[32] for example, is possible. The method relies on the identification of patterns of elemental responses as illustrated in Figure 11 for three separate analyses over three months of steel from five safes; four groups of elements are compared. These so-called *ternary plots* represent the direct comparison of the relationship between three components in a system. For data to plot in any corner of a triangle, representing the ternary association of the three components, would indicate that the concentration of that component indicated at the corner was 100% relative to the other two components.

While samples with different provenance will be discriminated in ternary plots by a suitable choice of analytes, samples with the same provenance will not be discriminated under any variation of analytes. The plots of Figure 11, for example, show a tight packed relation for safes 3 and 5 in all but the last (lower right), the latter indicating a different provenance. This fingerprinting technique has already proved a practical success in forensic science.

The ability to provide spatially-resolved analysis is one of the anticipated advantages ofLA/ICP-spectrometry, and has been markedly improved over the last ten years. Ablation by single laser shots, multiple shots on the same site, individual sites in a row or in a plane in principle allow the analysis of individual grains, the production of

depth profiles, line profiles, or area analyses, respectively. Of major importance to the analytical performance of laser microprobe/inductively coupled plasma/mass spectrometry (LM/ICP/MS) is the spatial resolution. Some of the early studies in which improved laser optics allowed the ablation crater diameter to be reduced from 150 μm to about 25 μm are briefly reviewed elsewhere.[33]

Moissette et al.[34] used pulses at 266 nm from a Nd : YAG laser operated at 10 Hz to ablate synthetic fluid inclusions in halite, microwells containing aqueous solutions, and glass reference materials. In this field, elemental intensities are reported as ratios to Na but owing to difficulties in measuring this element were reported ratioed to Sr (7440-24-6). Elemental ratios for Li (7439-93-2), Mg, K (7440-09-7), Ca, Mn, Cu (7440-50-8), Zn (7440-66-6), Rb, Cs, Ba, Pb (7439-92-1), B (7440-42-8), Cl (7782-50-5) and Br (7726-95-6) in the synthetic fluid inclusions were linear over several orders of

magnitude and in close agreement with those for the NIST SRM 611 glass and microwell solutions, irrespective of the inclusion size (20–100 μm) and depth in the sample (up to 80 μm). Thus microwells and glasses constitute suitable alternatives to synthetic fluid inclusions for the calibration and routine analysis of natural fluid inclusions. Similarly, concentrations for Sr in the range 90 to 153 $\mu g\,g^{-1}$ and Rb (98 to 100 $\mu g\,g^{-1}$) were determined in large (up to 1 mm diameter) fluid inclusions in halite[35] with precisions of 5–31%.

Further improvement in analytical performance is expected from the use of excimer lasers with wavelengths below 200 nm. The output from these devices gives extremely well-defined ablation pits and is also expected to produce less severe fractionation effects. Successful application of such instruments requires more sophisticated laser optics than used hitherto. Such a system, incorporating an argon fluoride 193 nm excimer laser, has been mounted, with a common UV/visual objective on a modified petrographic microscope with reflected and transmitted light illumination.[36] The improved beam quality allows the ablation of pits of only 4 μm diameter, giving DLs of $<10\,\mu g\,g^{-1}$ for selected elements between Rb and U.

4.3 Biological Materials

The author and colleagues reported the bulk multielemental analysis of botanical material[37] and foodstuffs.[38] To illustrate the sensitivity even of early ruby laser and quadrupole instruments, Figure 12 shows a spectrum obtained by ablating NIST 1577a bovine liver with 10 1.4-J N-mode shots. Mercury and lead were present at 4 and $135\,ng\,g^{-1}$, respectively. The isotopes of Hg (7439-97-6), Pb, and Bi (7440-69-9) are clearly visible.

LM analysis (variously abbreviated in the literature as LM, LAM, or LAMP) now offers more sophisticated possibilities. Outridge and Evans,[39] for example, outlined the difficulties encountered in analyzing teeth with ablation by pulses of wavelengths of 532 and 266 nm, finding that the analysis is wavelength, beam energy, and matrix dependent. More successful was a minor and trace element analysis across the growth bands of a shellfish *Arctica islandica*, with the resulting elemental profile being used as an indicator of heavy metal pollution through time. A spatial resolution of $<10\,\mu m$ was provided by the UV laser employed.[40]

The improved analytical performance of LM/ICP/MS over the last five years has apparently been little applied to biological analyses and is open for exploitation.

Figure 12 Spectrum obtained by LA/ICP/MS analysis of animal tissue. See text for details. The ^{201}Hg integral was 11 171 counts; the total certified Hg concentration was $4\,ng\,g^{-1}$. (Reproduced from Durrant.[8])

Table 4 summarizes key features of studies of biological materials.

4.4 Polymers

Analysis of plastics is illustrated by the early work of Marshall et al.[42] Successful analysis of polyester and polypropylene is demonstrated by the concentration data, reproduced in Table 5.

Improvement in analytical figures of merit can be expected with the use of the latest laser technology. This has been shown for the determination of Al, Ba, Ca, Cd (7440-43-9), Mg, Sb, Sn (7440-31-5) and Ti in poly(vinyl)chloride using LA/ICP/OES by Mermet's group,[43] where DLs obtained using a UV laser compare favorably with those obtained by SN/ICP/OES.

4.5 Other Matrices

Table 6 gives details of the analysis of diverse matrices by LA/ICP/OES and LA/ICP/MS. In nuclear applications where analysis of radioactive or toxic materials is common a complete LA/ICP/MS system may be sealed in a glove box. Laser sampling may readily be performed

far from the spectrometer since extending the laser cell to spectrometer tubing produces very little reduction in analyte responses.

5 ISOTOPE RATIO ANALYSIS

Isotope ratios may readily be determined by SN/ICP/MS. Factors of importance in such determinations[53] include

- sensitivity and counting statistics
- dead time
- resolution and abundance sensitivity and
- mass bias.

Thus count rates well above background are required, but these must not be so high that the detector is overwhelmed. However, to a degree, a dead-time correction can be applied at the onset of saturation, thus extending the working concentration range. Peaks nominally one mass unit apart must be clearly resolved, but resolution improves at the cost of sensitivity, so over-resolution is to be avoided. In practice tailing of one peak into an adjacent peak also occurs and sufficient abundance sensitivity, as it is known, to resolve a small peak from an adjacent intense one is necessary. In addition, the measured isotope ratio may deviate from the true value as a function of the difference in mass between the two isotopes measured. This effect, known as mass bias, may

be measured by comparison with a standard of known isotopic composition.

Owing to these considerations and to the ICP being a fairly noisy source, the best precisions achievable by SN/ICP/MS are typically 0.1% RSD. Unfortunately, the addition of signal fluctuations associated with sample introduction by LA leads to even poorer precisions, rending useful isotopic ratio measurements by LA/ICP/MS extremely difficult.

In 1987, Tye et al.[54] reported the measurement of the ratios $U^{234}:U^{235}$, $U^{234}:U^{236}$ and $U^{235}:U^{236}$ in U_3O_8 with percentage RSDs of 1.340, 0.774 and 1.020 respectively.

Subsequent improvement in laser optics allowed the determination of $^{207}Pb:^{206}Pb$ ratios and hence the calculation of ages of zircons with a grain size of $>60\,\mu m$ and a ^{207}Pb concentration of $>3\,\mu g\,g^{-1}$, to within 1% of the ages determined from thermal ionization mass spectrometry (TIMS) measurements.[55] Precisions for the average of the mean $^{207}Pb:^{206}Pb$ ratios from different pits in one grain were generally <1.5%. Although U : Pb ratios could not be accurately or precisely determined by LM/ICP/MS, its performance was otherwise comparable to the specialized technique usually used for such measurements, namely the sensitive high-resolution ion microprobe (SHRIMP).

Relatively poor precision is the stumbling block to the wider useful application of LA/ICP/MS to isotope ratio measurements but is overcome by the use of more sophisticated high-resolution spectrometers. In magnetic sector instruments the sampling interface is held at a high potential, e.g. +8 kV, and the quadrupole analyzer is replaced by an electrostatic and a magnetic analyzer, which transmit ions by kinetic energy and m/z, respectively. Following this double focusing the transmitted ions are detected by a Faraday cup (or cups). An up-to-date, simple and concise introduction to such spectrometers is available.[56]

Use of LA with a magnetic sector mass analyzer equipped with seven Faraday detectors[57] allows the determination of Pb isotope ratios with precisions comparable to those obtained by TIMS.[58] In this analysis the isotopic composition of lead within NIST SRM 610 glass was measured using Q mode pulses of 2 mJ from a Nd : YAG laser for sample ablation. Craters of $<40\,\mu m$ diameter were produced, corresponding to a total ablated mass of Pb of about 9×10^{-11} g per crater. Simultaneous measurement of ^{202}Hg, ^{203}Tl, ^{204}Hg and ^{204}Pb, ^{205}Tl, ^{206}Pb, ^{207}Pb, and ^{208}Pb isotopes was made. As the ratio $^{205}Tl : {}^{203}Tl$ had previously been shown to be related to the mass bias, this ratio was measured and used to correct the measured lead isotope ratios. The response of an isotope of mercury, ^{204}Hg, overlapped with that of ^{204}Pb but was corrected by measurement of the ^{202}Hg isotope. Table 7 shows the lead isotope ratios for repeat analyses, together with the standard error. The mean and standard deviation of each set is also given and compared with data obtained by TIMS and, where available, by secondary ionization mass spectrometry (SIMS). The important feature of the data is the precision, which is comparable to that obtained by the traditional methods of choice for such analyses.

Although not illustrated by the above analysis, high-resolution spectrometers are often also able to resolve out interfering polyatomic species. For example, a resolution of 2500, defined as the mass M divided by the mass width ΔM, resolves $^{56}Fe^+$ from $^{40}Ar^{16}O^+$, thereby allowing determination of iron at m/z 56.

Another innovative approach to isotope ratio determinations was reported by Houk et al.[59] using a double quadrupole instrument. The rationale for such an instrument is to eliminate flicker noise from the LA process by splitting the ion beam into two, each part being sent to its own quadrupole mass analyzer and detector. The sample was ablated with pulses from a Nd : YAG laser frequency doubled to operate at 532 nm and operating at

15 Hz and about 70 mJ per pulse. Count rates obtained simultaneously at m/z 52 and 53 from the ablation of NIST SRM 1263 showed an RSD of 3%, but for the ratio of the two signals the RSD improved to 0.54%. When five consecutive ratios were averaged, the average of five such averaged ratios was 0.24%. The latter was improved to 0.058% by increasing the dwell time (the time spent in accumulating data) from 0.5 to 2.0 s. Such precisions, of ratios of isotopes of one element, are only slightly above the counting (Poisson) statistics limit.

6 PERFORMANCE AND STATUS

As we have noted, the anticipated advantages of LA/ICP/MS and LA/ICP/OES include little sample preparation, rapid sample throughput, and excellent DLs.

Occasionally no sample preparation is needed and this represents an enormous saving in the workload of a skilled analyst. Frequently, however, some sample manipulation is required for maximum analytical performance. Throughput, i.e. the number of samples analyzed per working day, is excellent, being at worst equal to that of SN/ICP/MS. The DLs achieved are element and matrix specific but are now $<1\ \mu g\ g^{-1}$ for ablated crater diameters of only 20–40 μm.[60]

Another anticipated advantage of LA/ICP/MS with a quadrupole spectrometer is a significant reduction in spectral interferences owing to a reduction in the water loading of the ICP. This reduces water-derived polyatomic species present below mass 80 in SN/ICP/MS analyses as indicated by the data of Mochizuki et al.[7]

Table 8 Comparison of background intensities obtained by LA and solution introduction methods

Mass	Molecule	Analyte isotope (abundance, %)	Ratio of peak integrals (laser/solution[a])

presented in Table 8. (The Ar dimers are not water-related and levels are essentially the same in both SN/ICP/MS and LA/ICP/MS).

The linear dynamic range of ICP spectrometry is so familiar to users that it is perhaps overlooked. When pulse counting and current detection are both used, as they are in some ICP/MS instruments, for low and high count rates, respectively, the linear dynamic range extends over seven orders of magnitude or more.

Difficulties in obtaining fully quantitative concentration data have been apparent since Gray's original feasibility study.[5] Ingenious methods of calibration and internal standardization have been developed, and improved precisions are obtained by the use of radiation in the UV or far UV instead of the IR. Figures of merit are further improved by the use of magnetic sector instruments, which are now in much wider use than in the early years following their introduction in 1988.

One contribution to inaccuracy and imprecision, however, has not been fully overcome, namely chemical fractionation. Some studies of this effect have been undertaken. For example, elements such as Nb (7440-03-1), Ta, Zr (2440-67-7), and Hf show decreased fractionation trends with respect to Si in NIST SRM 610 glass during repeated LA, while elements such as Rb, Sr, Pb, Ba, and Ca show increasing trends. The effect, greater for IR than for UV/LA,[61] may be due in part to the formation of a complex plasma which both ablates the sample and shields it from incoming laser light. In a comparison of the ablation of glass by pulses of wavelength 1064 nm (IR), 532 nm (green) and 266 nm (UV), elemental fractionation was dependent on the melting point of the elemental oxide only for the first two wavelengths.[62]

Relatively little fractionation may occur with ablation by excimer lasers,[63] though the evidence is not definitive and more studies are needed. Indeed, an important observation by Outridge et al.[64] is that fractionation may occur not only in ablation but also in the transport of material to the ICP. Thus many of the previous studies of this problem have concerned only the product of these two effects and are therefore somewhat inadequate.

Finally, LA/ICP/OES deserves mention. Generally, this technique is less sensitive than ICP/MS and does not offer isotope ratio measurements. Against this should be set its greater simplicity of operation and maintenance and lower capital cost. Moreover, ICP/OES is also less prone to matrix effects than ICP/MS. In short, LA/ICP/OES is a very powerful technique and has received relatively little attention here only because of the *relative* strength of LA/ICP/MS. It should also be noted that most of the comments given concerning LA/ICP/MS also apply to LA/ICP/OES. For example, fractionation leads to a sample unrepresentative of the

original material and this influences either technique. In contrast, polyatomic interferences are a problem specific to ICP/MS.

7 DEVELOPMENT PROSPECTS

Means to improve analytical performance in LA/ICP/MS will continue to be developed. The wider use of mixed-gas plasmas, for example, would be advantageous in LA/ICP/MS to increase sensitivities and reduce relative oxide levels.[65] A new soft ablation technique[66] in which a slowly ramped increase in laser power produces a smoother response profile has given Pb : U age data in excellent agreement with those obtained by TIMS and SIMS. The improvement in performance, attributed to reduced fractionation effects, clearly merits further study.

Perhaps the most exciting foreseeable developments, however, lie in alternative spectrometers. We have already met double quadrupole instruments, but these are likely to remain a research tool in selected laboratories only. Other candidates include Fourier transform ion cyclotron resonance (FTICR), ion trap (IT), and time-of-flight (TOF) instruments. The possible use of such systems is outlined by Hieftje et al.,[67] who also indicate why inductively coupled plasma/time-of-flight/mass spectrometry (ICP/TOF/MS) may be the most promising among them. A prototype instrument has already been used in conjunction with LA.[68] Indeed, this technique has recently been applied to the analysis of metals.[69] Here we may note that the advantages of ICP/TOF/MS include high ion transport efficiency, high sensitivity, and extremely fast ($<60\,\mu s$) spectral collection across the whole mass range.

The reader is also directed to other exciting applications of LA/ICP/MS indicated by recent literature, namely biological speciation[70] and archeological studies.[71] As we have seen, successful applications of LA/ICP/MS and LA/ICP/OES abound in metallurgy, geology, materials science, pollution studies, nuclear science, and so on; both techniques deserve greater attention from botanists, biologists, and medical scientists.

Concerning the development of new instrumentation, alternative analytical procedures, and novel applications, the next decade promises to be even more exciting than the last.

ABBREVIATIONS AND ACRONYMS

AES	Atomic Emission Spectrometry
DL	Detection Limit

On-line liquid chromatography/mass spectrometry (LC/MS) has become a powerful technique in environmental analysis because of the separation capabilities of liquid chromatography (LC) and the detection and identification potential of mass spectrometry (MS), the characteristics of both methods making coupling very attractive. Among the interfacing systems used to couple LC with MS, those based on the atmospheric pressure ionization (API) offer advantages in terms of sensitivity and capability to analyze highly polar, ionic, heat sensitive and high-molecular-weight substances. Further, the on-line coupling of chromatographic separations with element-selective detection systems such as inductively coupled plasma mass spectrometry (ICP/MS) is an attractive technique for trace element speciation.

The main advantage of LC/MS lies in its ability to provide qualitative information (including molecular mass and fragmentation pattern) on the detected peaks. In addition, when all the ionization parameters are optimized, quantitative analyses can be carried out and low detection limits (at the ppb level) are obtained performing selective ion detection.

In environmental analysis, universal, selective and sensitive methods are needed to afford the assay of a wide variety of target and nontarget substances. Even though gas chromatography/mass spectrometry (GC/MS) is extensively applied to the analysis of organic contaminants in several matrices, LC/MS offers major advantages over GC/MS for analyzing polar, nonvolatile and thermolabile compounds. Ultraviolet (UV) or diode-array detector (DAD) are commonly used to perform detection in high-performance liquid chromatography (HPLC). However, UV-based detection methods for HPLC have several disadvantages deriving from nonspecific detection and lack of sensitivity. A more reliable identification is sometimes possible using DAD for certain compound classes, e.g. nitrophenols, in environmental samples; however, structural information is lacking for some classes of pollutants, among which are some pesticides, because their UV spectra are often almost identical. Using unspecific LC detectors, detection may be complicated by false-positive results; in such cases, MS has proved to be an extremely valuable technique for unequivocal identification of microcontaminants in a variety of environmental samples.

This overview discusses recent instrumental developments concerning mass analyzers of the mass spectrometers and on-line sample treatment procedures, with emphasis on the environmental field. Among the environmental applications of LC/MS, methods for the analysis of pesticides, polycyclic aromatic hydrocarbons (PAHs), dyes, surfactants, inorganic and organometallic compounds in environmental samples are discussed.

1 INTRODUCTION

High-performance liquid chromatography/mass spectrometry (HPLC/MS) realizes the combination of an analytical liquid-phase-based separation with mass spectrometric analysis for determination of nonvolatile, polar, thermolabile and ionic compounds.

On-line LC/MS has become a powerful technique in qualitative and quantitative analysis also in the environmental field because of the separation capabilities of LC and the detection and identification potential of MS, the characteristics of both methods making coupling very attractive.

The interfacing of LC with MS has been the object of fervent research for almost 30 years, since the first studies of Tal'roze et al. in 1969.[1] Different approaches have been devised to provide an effective combination of these two techniques including direct liquid introduction (DLI),[2] moving belt (MB),[3] particle beam (PB),[4] thermospray (TS),[5] continuous-flow fast atom bombardment (CFFAB)[6] and more recently electrospray (ES),[7] pneumatically-assisted electrospray (PAES) or ionspray (IS)[8] and heated nebulizer/atmospheric pressure chemical ionization (HN/APCI).[9] Finally, the on-line coupling of chromatographic separations with element-selective detection systems such as ICP/MS is an attractive technique for trace element speciation.[10]

LC/MS has progressed rapidly in the last years because it has benefited from the marked development of atmospheric pressure MS sources utilizing ES ionization; these ionization techniques are capable of producing ions from highly polar, ionic, heat sensitive and high molecular-weight substances. The main advantage of LC/MS is its ability to provide qualitative information (including molecular mass and fragmentation pattern) on the detected peaks. In addition, when all the ionization parameters are optimized, quantitative analyses can be carried out and low limits of detection (LOD) (at the ppb level) are obtained performing selective ion detection; selective ion monitoring (SIM) acquisition is a useful approach to obtain maximum sensitivity in the quantitation of target compounds.

In environmental analysis, universal, selective and sensitive methods are needed to afford the assay of a wide variety of target and nontarget substances. Even though GC/MS is still the most popular technique for the analysis of toxic organic micro-contaminants in several matrices, LC/MS offers major advantages over GC/MS for analyzing polar, nonvolatile and thermolabile compounds. Conventional detection in HPLC is usually achieved with UV or DAD. However, UV-based methods of HPLC have several disadvantages deriving from nonspecific detection and lack of sensitivity. The most serious drawbacks of UV detectors arise from matrix interferences particularly when working at low wavelengths, since several compounds lack a strong chromophore in the UV region for sensitive detection. When using DAD, a more reliable identification in environmental samples is sometimes possible for certain compound classes, e.g. nitrophenols. However, structural information is lacking for some classes of pollutants, for example, some pesticides, because their UV spectra are often almost identical. Therefore, UV detection and DAD are not well suited for universal application. If unspecific LC detectors are used, detection may be complicated by false-positive results; in such cases, MS has proved to be an extremely valuable technique for unequivocal identification of micro-contaminants in a variety of environmental samples.

1.1 Mass Spectrometers: Characteristics and Recent Developments in Mass Analyzers

Recent instrumental improvements to LC/MS systems are related to the use of mass analyzers instead of the quadrupole mass spectrometers.

Quadrupole instruments are the most common in LC/MS applications in various research areas and also in the environmental field; the relatively low costs, the ease of operation and fast data acquisition account for the widespread use of this mass analyzer. Other features of the quadrupole are the adequate dynamic range, the unit-mass resolution and the good quantitation capabilities; the restricted mass range (up to 4000 Da) is the main drawback, even though it is not a problem in environmental analysis.

Quadrupoles are readily combined with other types of analyzers, including other quadrupoles in arrangements for tandem mass spectrometry (MS/MS) experiments; triple quadrupole mass spectrometers are used in MS/MS for enhanced selectivity and improved detectability in trace analysis. This subject will be discussed in the section 1.3.

Commercial LC/MS instruments are also based on ion trap (IT) technology; interesting features of an ion trap mass spectrometer (ITMS) are the high sensitivity due to ion accumulation capabilities (100 times higher than by scanning quadrupole MS), the specificity because of the MS/MS options, the unlimited mass range and the scanning speed. On the other hand, IT systems generally suffers from space charge effects, ion–molecule reactions and from a limited dynamic range. Multiple-stage tandem mass spectrometry (MS^n) experiments which can be performed with this mass analyzer make the ITMS attractive particularly in structure elucidation rather than in quantitative target compound analysis. It should be noted that commercial IT-based LC/MS instruments are considerably less expensive than triple quadrupole systems and thus they could be ideally suited for target-type screening procedures in environmental applications.

Another mass analyzer which shows good perspectives in environmental LC/MS analysis is the time-of-flight (TOF) instrument. Time-of-flight mass spectrometry (TOFMS) can provide high sensitivity and a fast acquisition rate, combined with higher mass accuracy compared with scanning techniques such as quadrupole MS; the last feature is especially important for high-resolution capillary separation methods, such as capillary HPLC and capillary electrophoresis. Since it is a non-scanning instrument, mass resolution is not related

to sensitivity, so that high sensitivity can be achieved with a reasonably high resolution. TOFMS can be used in combination with pulsed ion sources, such as matrix assisted laser desorption/ionization (MALDI) making this system particularly useful in biological applications where high-molecular mass compounds are to be analyzed.

The magnetic sector mass spectrometer is used in environmental applications which require very high resolution, to aid structural elucidation and confirm molecular formulae of toxic micro-contaminants. Besides accurate mass measurements, this instrument can provide several benefits such as good sensitivity and selectivity and an excellent dynamic range. The high costs of the equipment, the complexity of operation are the main drawbacks of the magnetic sector mass spectrometer. Further, because of the high vacuum requirements, the combination of this mass analyzer with high-pressure LC/MS interfacing/ionization systems is not ideally suited; in fact, the enhancement in sensitivity due to improved ion transmission efficiency in the sector falls off because of losses in ion transmission in the passage from the high-pressure ion source to the high-vacuum analyzer.

High-resolution measurements are achievable with the Fourier transform ion cyclotron resonance (FTICR) instrument; the exact mass assignment capabilities, the excellent sensitivity and the feasibility of performing multiple-stage MS/MS are outweighed by the high prices and the severe vacuum restrictions of this sophisticated mass analyzer. For these reasons, it is rarely used in environmental applications and is unlikely to be employed widely in this field in the future.

1.2 Chromatographic Mechanisms and Solvent Systems in Liquid Chromatography/Mass Spectrometry

LC/MS coupling often puts restrictions on LC flow range or mobile phase composition. The eluent flow-rate plays a very important role in interfacing to MS. As for PB, the acceptable liquid flows vary in the $100-1000\,\mu L\,min^{-1}$ range according to the different nebulizer designs.[11] With the TS interface the total effluent from a conventional HPLC column (over $1\,mL\,min^{-1}$ of an aqueous mobile phase) can be introduced directly into the MS vacuum system. Interfaces such CFFAB and ES can accommodate only limited flow-rates (about $5\,\mu L\,min^{-1}$), whereas IS is capable of operating at $50-100\,\mu L\,min^{-1}$ thanks to the independent pneumatic nebulization; for this reason, in research to develop the various LC/MS interfacing systems, considerable attention has been paid to miniaturization of the HPLC columns to obtain the required linear velocity, without the need for conventional post-column splitting for flow-rate reduction. On the other hand, various manufacturers have proposed the introduction of higher flow-rate ES interfaces, such as turbo-ionspray™ (Perkin-Elmer Sciex trademark), ultrasonically assisted ES, thermally assisted ES and various high-flow options to be used in combination with pneumatically assisted ES; these instrumental developments with reference to currently commercially available LC/MS interfaces are extensively discussed in a recent review paper.[12] Among the API techniques, HN/APCI offers high solvent flow-rate capability (up to $2\,mL\,min^{-1}$); further, this interface/ionization system is compatible with a variety of mobile phase compositions, including pure aqueous solvents, making this technique highly versatile. The need for using volatile buffers with the other interfaces is a serious drawback, since chromatographic mechanisms, such as ion-exchange and ion-pair (IP) LC, which are useful for separating analytes which are also of environmental concern, cannot be universally applied. A possible solution to the requirements of volatile buffers and ion-pairing agents involves either replacement of involatile compounds by volatile equivalents or post-column suppression techniques.[13,14] In target-compound analysis, the phase-system switching (PSS) approach, based on heart cutting using valve-switching and coupled-column techniques, is successfully used to overcome some of the compatibility problems; following this on-line post-column liquid–solid extraction, a trapping column at the outlet of the analytical column is used to connect HPLC containing nonvolatile buffers and IP agents in the mobile phase to the mass spectrometer.[14–17] Vreeken[18] extensively discussed the application of post-column liquid–solid extraction in liquid chromatography/thermospray/mass spectrometry (LC/TS/MS) in a book devoted to applications of LC/MS in the environmental field.

With regard to the on-line coupling with ICP/MS, ion chromatography (IC) and ion-pairing chromatography are frequently used for inorganic and organometallic speciation. IC can separate both organic and inorganic charged species and, since it requires low buffer and organic solvent concentrations, unlike IP chromatography, is more amenable for coupling with ICP/MS. In general, liquid chromatography/inductively coupled plasma/mass spectrometry (LC/ICP/MS) based methods require the appropriate choice of chromatographic and plasma conditions to obtain efficient separations and to maintain good detector performance by preventing blocking of the interface or extinguishing of the plasma. Organic solvents used in LC eluents can lessen the performance of plasma MS because of the instability of the plasma to organic vapors and deposition of carbon on the sampling cone and torch. Chromatographic solvents used in normal-phase (NP) partition or adsorption present difficulty for effective plasma interfacing. Reversed-phase (RP) HPLC is most acceptable in LC/ICP/MS experiments; however, as the

percentage of organic eluent components increases, increase of radio-frequency power and the use of water-cooled spray chamber to enhance condensation of volatile solvents is needed. One approach can be microbore HPLC, with lower mobile phase flow-rates and a simpler interface. Mobile phases containing salts can cause short-term signal fluctuation, affect signal-to-noise (S/N) and give a more complex mass spectrum, particularly for $m/z < 80$. In addition, the deposition of salts in the nebulizer and on the sampling cone can cause blockage.[19,20]

1.3 Tandem Mass Spectrometry and Related Techniques

Interfacing systems such as TS, electrospray/ionspray (ES/IS) and HN/APCI yield soft ionization which can be complemented by recourse to liquid chromatography/tandem mass spectrometry (LC/MS/MS) as realized with the use of a triple-quadrupole system or quadrupole ITs; in the case of the API techniques, collision-induced dissociation (CID) in the interface itself (in-source CID) can be invoked to obtain structural information.

The most common MS/MS operating modes of tandem mass spectrometers are precursor ion scan, neutral-loss or product-ion scan and the selective reaction monitoring (SRM) mode,[21] the operational mode chosen being dependent on the analytical information required. Precursor ion, neutral-loss and product-ion scan modes are very selective and thus useful in screening, but they lack the sensitivity necessary for trace analysis. Instead, the use of SRM provides adequate selectivity and sensitivity for the determination of trace compounds in quantitative environmental assay; the choice of a limited number of precursor ion-product IPs to be monitored affords maximal selectivity and better S/N ratio. Both triple quadrupoles and IT analyzers can be used to carry out MS/MS experiments in product-ion mode and SRM mode; with the IT instruments, multiple-stage MS/MS can also be performed, as discussed above (section 1.1).

The selectivity of MS/MS reduces the need for complete chromatographic resolution of individual components; in fact, LC/MS/MS methods may facilitate the identification of substances in unresolved LC peaks, since a full-scan CID mass spectrum is characteristic of the structure of the parent compound. Fast LC/MS/MS analysis reduces the analytical run time thus providing high sample throughput. In addition, in some cases the use of MS/MS equipment allows direct analysis of even complex mixtures without chromatographic separation, making flow injection analysis/tandem mass spectrometry (FIA/MS/MS) helpful for time-saving.

The power of LC/MS/MS as a technique for the detection of analytes of environmental concern has been successfully demonstrated for quantitative analysis particularly in selected reaction monitoring mode.[22]

2 ENVIRONMENTAL APPLICATIONS

LC/MS has acquired a role of growing importance in environmental analysis, as is attested by the variety of applications appearing in recent years in this field and by the large number of reviews[23–32] and books[33–35] on the subject. In a review dealing with the occurrence, sample handling and chromatographic determination of pesticides in the aquatic environment, Barceló[23] has discussed the choice of gas chromatography (GC) or LC methods in combination with MS for the unequivocal characterization of pesticides and their breakdown products in environmental samples. In another paper, Barceló[24] has reviewed different coupled techniques such as GC/MS, LC/MS and MS/MS for the analysis of polar pesticides, surfactants, PAHs and polychlorinated biphenyls. Advantages and limitations of different LC/MS interfacing systems with reference to selected biological and environmental applications are discussed by the same author.[25] Careri et al.[26] have highlighted features and limitations of the various LC/MS approaches in an overview dealing with the application of this combined technique for the analysis of pollutants (pesticides, PAHs, inorganic and organometallic compounds, surfactants and dyes). An authoritative review of LC/MS which describes both the interfacing techniques and applications in environmental field is that published by Slobodník et al.:[27] the application-oriented section of the overview primarily deals with polar pesticides and related substances with emphasis on the on-line and off-line trace enrichment procedures. Chromatographic methods for the analysis of various classes of surfactants (nonionic surfactants, polar aromatic surfactants) in environmental samples have been extensively reviewed in recent papers.[28–30] An overview of current analytical methods including LC/MS for the analysis of sulfonated azo dyes in environmental samples has been published by Riu et al.[31] More recently, Di Corcia[32] has reviewed the state-of-the-art in the characterization of complex mixtures of isomers, oligomers and homologs of surfactants as well as their biointermediates in environmental matrices using LC/MS methodologies.

2.1 Pesticides in Environmental Water Samples

LC/MS is now indispensable in environmental organic analysis and surpasses GC/MS in the determination of polar pesticides; unlike GC, LC is not restricted by compound volatility or thermal lability, from which some pesticides suffer. In this respect, carbamates, triazines

Table 1 The EC priority pollutants list

Class	Compound class[a]
OCP	Organochloro pesticides
CP	Chlorophenols
PAH	Polyaromatic hydrocarbons
INORG	Inorganic – metals
OPP	Organophosphorus pesticides
VA	Volatile aromatics
AA	Amino aromatics
VHO	Volatile halogenated organics
COH	Halogenated hydroxyl compounds
CCOOH	Halogenated carboxyl compounds
CA	Chloroanilines
CNB	Chloronitrobenzenes
SVHO	Semivolatile halogenated organics
CNT	Chloronitrotoluenes
CT	Chlorotoluidines
TRIA	Triazines
PhAP	Phenoxy acid pesticides
ORGSn	Organotin compounds
BDs	Benzidines
CE	Chloroethers
A	Amines
PU	Phenylurea compounds
MISC	Miscellaneous

[a] Nomenclature used by the EC.

(TRIA), phenylureas and their corresponding anilines, and chlorinated phenoxy acids are groups of pesticides for which methods using LC are usually applied, making this technique appealing for multiresidue analysis.

The large number of different pesticides used within the European Community (EC) requires the development of rapid screening multiresidue methods for as many as possible of the most relevant pollutants. In addition, a European Union directive[36] demands methods that allow the verification of the concentration limit of $100\,ng\,L^{-1}$ for individual pesticide species in water intended for human consumption, which means that analytical methods should be able to detect pesticides at about one-tenth of this limit or lower, i.e. $10–20\,ng\,L^{-1}$. In Table 1 the classes of pesticides included in the EC priority pollutant list are reported.

In the US system of environmental monitoring, the maximum contaminant levels set by the Environmental Protection Agency (EPA) National Primary Drinking Water Regulations are in the $2–700\,\mu g\,L^{-1}$ range;[37] these guidelines demand limits of 40 and $200\,\mu g\,L^{-1}$ for carbofuran and oxamyl among carbamates in water, whereas limits of 50 and $70\,\mu g\,L^{-1}$ are established for fenoprop (2,4,5-TP) and dichlor phenoxyacetic acid (2,4-D) among phenoxy acid herbicides.

Because it is applicable to a wide range of compounds and is rugged, the TS interface has dominated LC/MS applications for pesticide analysis in environmental samples over the past 10 years. Thermospray mass spectrometry (TS/MS) is mainly used for target compound analysis rather than for the identification of unknown compounds in the environmental field; in fact, TS mass spectra often yield scarce fragmentation and thus lack structural information. To overcome this drawback, several approaches have been used, e.g. different ionization modes (the filament-on mode and the discharge ionization mode)[38] or the coupling of the TS interface with MS/MS.[39] The MS/MS approach is an elegant way of achieving relevant structural information, even though at the cost of a greater complexity of the technique; it is also highly useful for the characterization of unknown pesticide metabolites formed during degradation processes. Complementary information can also be gained exploiting both positive-ion (PI) and negative-ion (NI) operational modes.[40]

LC/MS with the PB interface is effective in the analysis of medium-polarity low-mass analytes of environmental concern. The combination of retention times, electron impact (EI) mass spectra and isotope distribution patterns for compounds containing naturally occurring isotopes provides excellent information for the unambiguous identification of both target and unknown compounds. The nonlinearity effects at low concentrations and the low sensitivity are the major drawbacks in the quantitative analysis performed by particle beam/mass spectrometry (PB/MS); better quantitative results in terms of linearity and detection limits can be achieved when operating in the presence of mobile phase additives or co-eluting internal standards.[11]

In Table 2 the most important classes of pesticides are briefly summarized, together with the LC/MS interfacing techniques used for their determination and the corresponding references.[17,41–53] To date LC/TS/MS and LC/PB/MS have been largely replaced by API techniques ES/IS and atmospheric pressure chemical ionization (APCI); the number of reports dealing with the application of electrospray/mass spectrometry (ES/MS) and HN/APCI/MS in pesticide analysis is rapidly growing. For this reason, this article will cover the most recent application examples in which the API techniques are used. Selected examples of multiresidue analyses of polar pesticides in environmental water samples (drinking water, ground- and surface waters) will be described in the following sections. Polar pesticides (phenylurea, sulfonylurea, phenoxy acid and triazine herbicides, carbamates, phenols, organophosphorus compounds) are considered, since they have become an important part of groundwater monitoring programmes, being the most likely to leach to groundwater.

Solid-phase extraction (SPE) for the preconcentration of the organic micropollutants is usually carried out; in some cases on-line monitoring procedures have been

proposed. The combination of sample treatment by means of SPE with LC/MS in one set-up will be thoroughly discussed in section 3.

2.1.1 Triazines, Phenylureas, Anilides, Carbamates, Organophosphates, Nitrophenols

Column LC with IS or APCI interfaces using MS or MS/MS has been used for the analysis of 17 pesticides belonging to the cited classes in tap and surface waters.[48] Surface water samples were spiked with propazine (CAS 139-40-2) and metoxuron (CAS 19937-59-8) as internal standards. Sample aliquots were preconcentrated on PLRP-S (styrene–divinylbenzene copolymer) cartridges. Separations were performed on a C_{18} column, using acetonitrile–water as the mobile phase. The use of the on-line SPE/LC/API/MS/MS system made it possible to achieve detection limits at low nanograms per liter levels (Table 3). Negative ion acquisition mode was in most cases less sensitive, but organophosphorus compounds and nitrophenols gave adequate signals only in the NI mode. Detection limits obtained with APCI and IS interfaces are similar for the most compounds. However, the IS system appeared to be more prone

Table 3 Detection limits (S/N ratio 3) of 17 pesticides obtained from SPE/LC/PAES/MS and SPE/LC/APCI/MS in full-scan, SIM and MS/MS modes, using 100-mL samples[48]

to the formation of alkali metal adducts and the ion intensities were strongly dependent on the amount of sodium or potassium deriving from glassware and solvents. LC/APCI/MS in the PI mode appears to be the preferred method for the analysis of the classes of pesticides investigated, except for the organophosphorus compounds (Figure 1).

In MS/MS experiments, the excellent sensitivity of the SIM mode required for trace-level determination of pesticide residues can be combined with the capability in obtaining diagnostic product-ion spectra; Figure 2 shows the APCI and IS product-ion spectra obtained from protonated molecules of pesticides belonging to different classes. The acquisition of MS/MS spectra makes it possible to compile a library of product-ion spectra for the identification of the analytes in real samples.

2.1.2 Acidic Pesticides (Phenoxy Acids, Sulfonylureas, Phenols)

PAES interface has been used for the determination of 18 pesticides, including phenoxy acids, sulfonylureas, phenols, or their degradation products in groundwater samples by means of LC/MS and LC/MS/MS.[46]

To obtain satisfactory chromatographic results with these acidic analytes in terms of peak resolution, ion suppression with an acidic mobile phase is necessary. The chromatographic separation was obtained on a C_{18} narrow-bore column with a gradient elution of methanol–water–acetic acid. Porapak SPE cartridges were used for sample clean-up. Because of the acidic characteristics of the pesticides tested, mass analysis was performed under NI conditions in SIM mode; MS/MS experiments were performed in product-ion scanning mode or SRM mode. The highest sensitivity was achieved using MS and SIM detection. On the other hand, CID MS/MS experiments give a higher degree of confidence in the identification of the compounds by providing structural information.

In Table 4, in addition to the list of the analytes considered, comparison of the instrumental LOD obtained in the two MS detection modes is reported. For most compounds, LOD were three–four times lower using MS with respect to CID MS/MS. LC/IS/MS response was linear in the $5–500\,\mu g\,L^{-1}$ range for most analytes, except for four phenols [DNOC, dinoseb, bromoxynil and ioxynil] and bentazon. The method detection limits (MDLs) were determined on tap water samples spiked with the pesticides, using single MS in SIM mode. The results together with recovery values and precision are quoted in Table 5. The method was then applied to real samples of groundwater, which were first analyzed for the target herbicides using single MS in SIM mode. Positive findings were verified in a subsequent run using MS/MS in SRM mode by detecting diagnostic product ions. An example is reported in Figure 3; the concentration of phenoxy acids determined in the sample were $0.012\,\mu g\,L^{-1}$ of 2,4-D, $0.006\,\mu g\,L^{-1}$ of dichlorprop and $0.010\,\mu g\,L^{-1}$ of MCPA.

Figure 1 Chromatograms of the mixture of 17 pesticides obtained by (a) LC/UV, (b) on-line SPE/LC/APCI/MS and (c) SPE/LC/PAES/MS. Injected amount in (a) is 125 ng of each pesticide; the UV detector was kept at 215 nm. Enriched volume in (b) and (c) is 100 mL tap water; concentration of each analyte is 2.5 $\mu g\,L^{-1}$, MS is operated in full-scan mode, scan range m/z 150–420. Peaks: 1: oxamyl; 2: dimethoate; 3: aldicarb; 4: monuron; 5: propoxur; 6: diuron; 7: propazine; 8: terbutylazine; 9: fenamiphos; 10: alachlor; 11: neburon; 12: fenthion; 13: coumaphos; 14: fenchlorphos; 15: chlorpyriphos; 16: trifluralin; 17: bromophos-ethyl. A*, **741**, 59–74 © 1996.)

2.1.3 Carbamates

Ten carbamate pesticides of widely varying polarity were determined in waters and sediments using LC/IS/MS.[51] Concerning the interfacing conditions, the optimum cone extraction voltage with respect to analyte detectability and identification capabilities was between 15 and 35 V; this parameter is known to affect the sampling efficiencies in API sources.[54] In the mass spectra of most compounds the sodium adduct ion was the base peak. Chromatographic separations were performed on a reversed phase column using methanol–water mixtures as the eluent in gradient mode. The detection limits (S/N = 5–10) obtained with LC/IS/MS were in the 10–60 pg range (Table 6); linearity was checked in the 5–400 $\mu g\,L^{-1}$ range.

Concerning the applications, estuarine water samples were preconcentrated using liquid–solid extraction by passing 2 L of sample on C_{18}-bonded silica disks; the pesticides were recovered by two extractions with 10 mL of acetonitrile; after evaporation, the samples were dissolved in methanol and injected. Figure 4 shows the chromatogram of a surface water sample from the Ebro river and the mass spectrum of the peak eluting at 20 min, which allows the identification of carbofuran at low concentration levels, that is, at a concentration of about 1 $ng\,L^{-1}$ in the original water sample. Large-volume injections (500 µL) of tap water spiked at a level of 0.1 $\mu g\,L^{-1}$ of selected carbamates demonstrated the potential of LC/IS/MS with respect to trace-level detectability, making feasible the assay of these pollutants at levels below those of EU drinking water directives.[36]

2.1.4 Organophosphorus Pesticides

Twelve OPP have been determined in groundwater using LC/APCI/MS.[53] In Figure 5 the formulae of the

Figure 2 Product-ion spectra from protonated molecules of fenamiphos, alachlor, propazine and diuron in (a) PAES/MS/MS and (b) APCI/MS/MS. The APCI experiment was performed with injections of 125 ng of each compound onto a single short column. Temperature of the ion source, 150 °C; LC eluent flow-rate, 1 mL min^{-1}. The PAES/MS/MS spectra were obtained at a flow-rate of 25 µL min^{-1}; temperature of the ion source, 70 °C. (Reproduced by permission of Elsevier Science Publishers B.V. from J. Slobodník, A.C. Hogenboom, J.J. Vreuls, J.A. Rontree, B.L.M. van Baar, W.M.A. Niessen, U.A.Th. Brinkman, *J. Chromatogr. A*, **741**, 59–74 © 1996.)

considered analytes are reported. An automated on-line liquid–solid extraction procedure was applied on RP (C_{18}) cartridges. Separation was achieved using a C_8 column and a gradient elution of methanol–water (1% acetic acid). Using APCI/MS with time-scheduled SIM in PI mode, the detection and quantitation limits reported in Table 7 were obtained. At the limit of quantitation (LOQ) concentration level, repeatability ($n = 5$) ranged from 17 to 25%. Operating in NI acquisition mode, best results were obtained for the parathion group compounds, whereas for the other compounds higher LOQs than those obtained acquiring the PI signals were achieved. Calibration graphs were linear in the range 0.0125–1 ng mL^{-1} for most of the analytes using SIM in PI or NI mode. Figure 6 shows the chromatograms for 100 mL of water samples spiked with 1000 ng L^{-1} of the OPP. The method was validated by analyzing certified samples of groundwater containing organophosphorus derivatives at levels between 10 and 100 ng L^{-1}.

In a recent study, the effects of the probe temperature and of extraction voltage on the fragmentation of the OPP were investigated with the aim of finding the best sensitivity and structural information for identification purposes;[54] compounds having the P=S bond were found to be more thermally stable with respect to those containing the P=O bond. In general, the optimum conditions as regards to flow-rate, probe temperature and extraction voltage were 1.2 mL min^{-1}, 400 °C and 20 V, respectively, even though for some compounds, e.g. trichlorfon (CAS 52-68-6), thermal degradation was observed. For these low thermolabile compounds ES/MS

is likely the most suitable technique, whereas the other polar OPP and the parathion group are more amenable for LC/APCI/MS analysis.

The examples described prove that LC/MS with IS or APCI interfaces provides instrumental detection limits, which make possible determinations of pesticides in environmental water samples at concentration levels below those of the EC Council directive 80/778/EEC ($0.1\,\mu g\,L^{-1}$ for individual pesticide).

2.2 Polycyclic Aromatic Hydrocarbons

The presence of PAHs in environmental samples is a legitimate cause for concern, because some PAHs are found to be highly carcinogenic.[55] Widespread in the environment, they originate from the incomplete combustion of organic material from both natural and anthropogenic sources;[55] PAHs have been observed in airborne particulates, coal soot, coal tar, particulate exhaust emissions of diesel- and gasoline-powered engines, marine sediments and water samples.

Owing to the carcinogenic properties of some of these substances, selective and sensitive analytical methods are required to assess their potential health risk and their impact in the environment. PAHs are priority pollutants on both the EC (Table 1) and US EPA lists. PAH determination is mostly limited to the analysis of 16 compounds (EC, EPA) (Table 8) in drinking, surface and wastewater by HPLC and HPLC/MS. A limit of $200\,ng\,L^{-1}$ of benzo[*a*]pyrene (CAS 50-32-8) in drinking water is set by the Office of Water of US

Figure 3 Typical chromatograms from an LC/ES/MS analysis of an authentic groundwater sample following pre-concentration by solid phase extraction. The sample was analyzed using single MS in SIM mode (a) and, subsequently, by MS/MS in SRM mode (b) for verification. Compound identification: 1: MCPA; 2: 2,4-D; 3: dichlorprop. EPA.[37] The same tolerance level has been established in Directives of the Commission of the European Economic Communities.[36]

A number of SRMs have been issued by the US National Institute of Standards and Technology (NIST) to assist in validating the accuracy of PAH determinations. These SRMs range from a standard solution of 16 priority pollutant PAHs in acetonitrile (SRM 1647) to a complex mixture of PAHs from coal tar (SRM 1597), from air particulate material (SRM 1649) and from diesel particulate matter (SRM 1650).

The analysis and detection of PAHs in complex environmental samples is possible by a large number of different chromatographic methods; capillary GC combined with MS has been shown to be a very selective and sensitive analytical technique, even though its applicability is limited by the low volatility of high-molecular weight PAHs. Larger derivatives are more easily analyzed by LC methods using spectrophotometric or spectrofluorimetric detectors; on the other hand, the lower efficiency of LC demands the use of more selective detection methods, such as MS. A survey of the applications of LC/MS methods in the analysis of PAHs is shown in Table 9.[56] In the past MB and PB have been the interfacing systems most frequently used for the LC/MS assay of these low-polar analytes.[56–60,63] Generally, using the PB interface detection limits in the nanogram

Figure 4 LC/IS/MS ion chromatogram of the ion at *m/z* 244 obtained after full-scan (*m/z* 50–300) acquisition and injecting 25 μL of a water sample (after 4000-fold preconcentration) from the Ebro river on to a 12.5 cm × 3 mm i.d. LC column. LC eluent flow-rate, 0.3 mL min^{-1}; extraction voltage, 60 V. The mass spectrum of the peak at a retention time of 20 min, shown as an inset, could be attributed to carbofuran ($[M + Na]^+$, *m/z* 244). range were reported for PAHs containing four or more rings;[58,59] in particular, PB/MS detection affords to obtain detection limits of 0.2, 0.5, 1 and 2 ng for chrysene, benzo[*g*,*h*,*i*]perylene, dibenzo[*a*,*h*]anthracene and coronene (CAS 191-07-1) respectively.[59] In a more recent work, the HN/APCI interface for LC/MS has been demonstrated to be the most suitable technique for trace-level determination of PAHs;[60] in contrast to LC/PB/MS, the LC/HN/APCI/MS system yields a response linearity of at most three orders of magnitude and LOD in the picogram range for both low- and high-molecular-weight congeners. Positive ion APCI mass spectra of PAHs are characterized by both molecular ions and protonated molecules with no fragmentation; proton transfer from protonated water clusters leading to MH^+ results to prevail over electron transfer to species such as

$N_2^{\bullet+}$ and $O_2^{\bullet+}$ with formation of M^+ as the size of the PAHs increases. The potential of the LC/HN/APCI/MS technique was demonstrated for a NIST certified coal tar reference material (SRM 1597), which is a natural, complex mixture of PAHs isolated from coal tar and certified for concentrations of 12 PAHs ranging from naphthalene to benzo[*g*,*h*,*i*]perylene. Internal standardization with perdeuterated PAH standards was used to perform the quantitative assay of the analytes using both the PB and APCI systems; in the first case, only seven out of 17 PAHs were detected, because of the poor transfer through the interface of the PAHs having molecular weights lower than 200 or greater than 380 Da. Conversely, using APCI interface all 17 of the target compounds were detected and accurately quantified; in general, satisfactory agreement with certified concentrations was observed when perdeuterated internal standards were used. The results of both PB and APCI measurements are summarized in Table 10.

PAHs, which are neutral low-polar compounds, cannot be detected under normal ES/MS conditions. The advantage of charge-transfer complexation to yield radical cations in solution for neutral substances for subsequent ES experiments has been demonstrated by Van Berkel et al.[61,62] However, ES/MS techniques do

not provide adequate sensitivity for trace environmental analysis of PAHs.

2.3 Dyes

Dyes are widely used in industrial applications including textile dyes, printing inks, paint pigments, foodstuffs, plastics and cosmetics.[64] The textile industry is the largest consumer of these chemicals and accounts for two-thirds of the dyestuff market.[65] Dyes encompass structures that include (sulfonated) azo, anthraquinone, phthalocyanine, arylmethane and coumarin moieties. Azo dyes represent approximately 50% of the dyes available on the market today; they are classified in azo, diazo, triazo classes and found in various categories, e.g. acid, basic, disperse and pigments. The manufacturing and use of dyes creates wastes, which are discharged with the effluents into the receiving waters, thus making the determination of these chemicals in water samples an important task for environmental analysis. These products represent a potential human health risk because of their toxicity or carcinogenicity; in addition, for intermediates formed during the synthesis of dyes and degradation products of dyestuffs, such as naphthylamines, substituted phenylamines or BD analogs, mutagenic and carcinogenic activity is also suspected.[66]

Synthetic dyes are very polar or ionic and thermally labile substances, so that they are beyond the reach of capillary GC. Analytical methods for azo dyes are mostly based on HPLC with ultraviolet/visible (UV/VIS) detection; recently, the US EPA has approved several LC and LC/MS methods including Method 553 for BDs, which are carcinogenic compounds formed during synthesis of dyes.[67]

Various types of LC/MS set-up have been proposed for the analysis of dyes, with particular attention to azo dyes (Table 11). Scarce structural information and poor sensitivity were obtained using TS LC/MS under both PI and NI conditions;[68–70,73,75] in order to better characterize the dyes, the LC/TS/MS/MS approach proved to be useful.[70] Valuable MS data for the structural elucidation of dyes have been obtained using the LC/MS system with the PB interface;[73,74] again low sensitivity with detection limits in the 0.5–5 μg range were achieved.[74] A comparison of TS and PB mass spectra of an azo dye is shown in Figure 7. An application of capillary liquid chromatography (CLC) coupled with CFLSI/MS has been reported by Brumley et al.;[75] seven monosulfonated dyes with azo, diazo, triarylmethane and anthraquinone groups were considered among synthetic dyes. Using CFLSI/MS as a detection system for capillary LC, mass peak-profiling at high mass resolution was demonstrated as a potentially useful tool in the structure elucidation of unknowns (Figure 8).

The feasibility of API techniques for LC/MS and LC/MS/MS of azo dyes have been demonstrated by several authors.[71,72,74,76] A pioneering study on LC/MS analysis of sulfonated azo dyes is that of Bruins et al.,[71] who used HN/APCI and IS interfacing systems in NI mode. Compounds having acidic functional groups are most suited for negative ion mode LC/MS because of their acidic properties. Disulfonated azo dyes were found to be more difficult to analyze by MS than the monosulfonated derivatives; the NI APCI spectra are given in Tables 12 and 13. By comparing the two interface systems, sensitivity for sulfonated azo dyes obtained with IS was remarkably higher than by HN/APCI. By performing liquid-phase ionization by IS, sensitivity was 10 times

higher for mono- than for disulfonated derivatives and the detection of approximately 10 ng of a monosulfonated product was demonstrated in full-scan conditions. Gas-phase ionization by APCI was 20–50 times less sensitive for disulfonated azo dyes compared with monosulfonated ones. Using LC/IS/MS/MS, product-ion spectra were generated by CID from the parent ions $[M - H]^-$; the $SO_3^{\bullet -}$ ion at *m/z* 80 was found to be a diagnostic fragment in the MS/MS analysis of this class of dyes so that SRM of the fragmentation reactions $[M - H]^- \longrightarrow SO_3^{\bullet -}$ for each analyte could afford selective detection of the dyes, as illustrated in Figure 9.

The better suitability of IS with respect to APCI for this class of substances has been more recently confirmed by Ràfols and Barceló[76] (Tables 14 and 15). On the other hand, using APCI in PI mode these authors observed a much better sensitivity towards disulfonated azo dyes than that previously found,[71] likely owing to a more efficient nebulization in the APCI interface.

Figure 8 Mass peak-profiling at 10000 resolution on CLC/MS chromatographic peaks: *m/z* 341.0596 of orange 8 and *m/z* 367.1816 of glycerol matrix as the lock mass. 2.4 Surfactants and their Biodegradation Products in Wastewater, Surface Water and Drinking Water

Surfactants are environmentally relevant because they are extensively used and occur at high levels of concentration in water.[77] These chemicals are used in large volumes both industrially and domestically in a broad variety of detergents and cleaning products. Surfactants have hydrophilic and hydrophobic centers both of which influence their physical and chemical properties; they may be classified as anionic surfactants, e.g. alkylbenzenesulfonates, cationic surfactants, e.g. quaternary ammonium salts, and nonionic surfactants such as those produced by reacting alkylphenols with ethylene oxide. General formulae and acronyms of the most widespreadly used anionic and nonionic surfactants which are discussed in

this article are reported in Table 16. Table 17 summarizes selected applications of LC/MS-based methods for the analysis of surfactants in water samples.

2.4.1 Anionic Surfactants

Anionic surfactants have been extensively studied in aquatic environments; particular attention has been paid to LAS due to their biodegradability which makes them potentially hazardous with respect to surface and groundwater, affecting also drinking water quality. LAS (Table 16) are water-soluble materials used extensively in detergent formulations as surface-active agents.

Commercial LAS materials consist of a mixture of homologs and isomers. Individual LAS homologs and isomers are identified by the length of the hydrophobic alkyl substituent and by the position of attachment of the alkyl chain to the benzene ring.

Other anionic surfactants commonly used in consumer products are AES and AS. After use, the majority of sulfonate and sulfate surfactants is disposed to sewage treatment plants (STPs); during the sewage treatment process anionic surfactants are extensively removed as the result of biodegradation processes[78] and adsorption to solids.[79]

Growing attention is being paid to the analysis of the degradation products of commonly used surfactants; concerning LAS, their biotransformation leads to the formation of mono- and dicarboxylic sulfophenyl acids via the w-oxidation of the alkyl chain.[80] In support of biodegradation and ecotoxicological studies, reliable analytical methodologies are required to determine these

substances at trace levels in wastewater treatment plant influents and effluents, as well as river waters. Various analytical methods are available for the measurement of these chemicals, including simple colorimetric methods, GC and LC, as well as MS methodologies. Anionic surfactants are not sufficiently volatile to permit direct measurement by GC; as a result, they must be either derivatized to form a volatile compound or, in the case of LAS, desulfonated to form the respective linear alkylbenzenes. HPLC has been widely applied to the measurement of these surfactants both in NP and in RP in conjunction with UV and fluorimetric detection. IP RP LC, which has become the method of choice for the separation of sulfonates and their degradation products sulfophenyl carboxylates, is incompatible with MS detection (section 1.2). An elegant approach was that of coupling LC to IS/MS via a postsuppressor split with an IC system for the separation and detection of alkyl sulfates and sulfonates;[13] the function of the micromembrane suppressor was that of removing over 99.9% of the IP agents required for the chromatography from the mobile phase. LC/MS has recently been applied widely to the analysis of anionic surfactants and their degradation biointermediates in water (Table 17).[13,79–82] A comprehensive review on the use of TS interface for LC/MS and flow injection analysis/mass spectrometry (FIA/MS) analysis of these chemicals and the corresponding metabolites has been written by Schröeder.[83] Anionic surfactants have been detected either in PI mode as MNH_4^+ adduct ions in LC/TS/MS[79] or as MNa^+ adduct ions in LC/APCI/MS,[80] or in the NI mode as deprotonated molecules using TS/MS[79] or ES/MS detection systems.[13,81] LC/MS with ES ionization has been proved ideally suited for trace-level identification and quantification of anionic surfactants;[81] a quantitative LC/MS method for the determination of AES in environmental samples using IS interface has been validated for three aqueous samples, i.e. sewage influent, sewage effluent and river water. Detection of 36 components, down to ppb levels, was feasible in full-scan mode with a single injection, whereas multiple injections in SIM conditions allowed one to determine 50-fold lower concentrations, limits-of-detection being about $0.01\,\mu g\,L^{-1}$ for most of the analytes in river water.

2.4.2 Nonionic Surfactants

Nonionic surfactants represent the second most important class of surfactants after the anionic class. The three nonionic surfactants discussed here are those listed in Table 16. AEOs were introduced for replacing the more toxic OPEOs and NPEOs and are being used increasingly both in the household and in industry. Although APEOs and AEOs are not classified as dangerous substances, investigation on the removal efficiency of these organics by STPs and their ecotoxicological impact on aquatic life demands the development of appropriate analytical methods able to determine them in influents and effluents of STPs as well as in the natural aquatic environment. Chronic toxicity data of nonionic surfactants to aquatic life forms such as algae, fish and invertebrates range from 0.1 to $20\,mg\,L^{-1}$, depending on substance structures and experimental conditions. In addition, more toxic degradation products of nonionic surfactants can be produced as a consequence of the metabolic activities of aquatic microbial communities. The PEG family has been indicated as primary key intermediates of the aerobic biodegradation of AEOs.[78] The progressive hydrolytic shortening of the polyethoxy chain of NPEOs leading mainly to the formation of metabolites with one and two ethoxy units together with nonylphenol is the most favored pathway of APEO aerobic biodegradation.[84] Nonylphenol and octylphenol have been reported to display oestrogenic activity, being suspected of altering reproduction in fish.[85]

NP HPLC and RP HPLC have been used to separate and determine the homologs and oligomers of nonionic surfactants by the alkyl chain and ethoxylate lengths. If HPLC with fluorimetric detection provides the most simple and suitable technique for the analysis of these compounds in environmental samples, on the other hand LC/MS offers a unique possibility for obtaining information on the occurrence and distribution of homologs, oligomers and isomers at the ppb level. Also investigation on PEG-type compounds in the aquatic environment is made easier by the use of LC/MS methodologies; in fact, the high polarity of these metabolites combined with the lack of any chromophore group in their structures makes them not amenable to GC and LC determination. Nonionic surfactants and their biointermediates have been analyzed using TS,[79,86] and ES[87] interfaces for LC/MS. LC/TS/MS has been proven to exhibit adequate sensitivity and selectivity for AEO determination, allowing the quantitation of total and individual alcoholethoxylate species at the ppb level. In addition, the technique discriminates branched AEO from linear ethylene-based AEO, which may co-elute. The on-line coupling of solid phase extraction with LC/TS/MS used for the enrichment of AEOs from groundwater and wastewater allowed to quantify individual alcohol ethoxylates in the 60 ppt and 2.17 ppb range.[86] In another study,[79] the comparison between the results obtained by LC/TS/MS and those from flow injection analysis/thermospray/mass spectrometry (FIA/TS/MS) analyses of AEOs and their metabolites in wastewater samples showed that the chromatographic separation does not contribute significantly to the information obtainable by the direct injection of the extracts in flow injection analysis (FIA) mode.

In addition, since determination by LC/MS took 25–30 times longer than FIA/MS, this technique provided higher sample throughout.

Recently, the LC/MS technique with ES interface has been promising in terms of sensitivity and selectivity for the analysis of nonionic polyethoxylate surfactants, such as AEOs and NPEOs in various environmental aqueous samples (influent and effluent waters from STPs, river waters, drinking waters).[87] An extraction/enrichment procedure involving the application of large water volumes (up to four liters) on a graphitized carbon black cartridge allowed to differentially elute the AEOs and NPEOs and their biointermediates according to differences in their acid strengths. The chromatographic method developed could afford the elution of all the oligomers of NPEO and of the various AEO homologs into single peaks (Figure 10), in such a way that quantitative assay was simplified and detection levels improved. The resulting detection limits for each single homolog of AEO and for NPEOs in the influent, effluent, river water and drinking water samples investigated were estimated to be 0.6, 0.02, 0.002 and 0.0002 $\mu g\,L^{-1}$ respectively. The selectivity and sensitivity of the method is illustrated in the chromatograms obtained by analyzing 4-liter tap water samples (Figure 11).

Efforts to characterize the degradation intermediates of nonionic surfactants in environmental matrices have increased in recent years. Concerning the metabolites of AEOs, TS/MS and thermospray tandem mass spectrometry (TS/MS/MS) techniques have been successfully used for the analysis of PEGs in various aqueous samples;[83] mass trace analysis allowed detection of individual PEG homologs of the general empirical formula $HO-(CH_2-CH_2-O)_nH$ $[n = 5–13]$ at low concentrations, whereas these compounds were not observed in the reconstructed ion chromatogram (RIC). An ES/MS-based method[87] was shown not to be adequate for the detection of degradation products of NPEOs containing one or two ethoxy units; this result provided low accuracy in the quantitation of NPEOs in STP effluents, since the oligomer distribution of a biodegradated NPEO mixture is different from that of NPEOs in the calibrated standard solutions.

Figure 10 (a) LC/MS chromatogram obtained by injecting the composite working standard solution containing NPEOs and AEOs. The analytes in this synthetic mixture are, in order of elution: 1: NPEOs; 2: C-12 ethoxylates (EOs); 3: C-13 EOs; 4: C-14 EOs; 5: C-15 EOs; 6: C-16 EOs, 7: C-18 EOs. Internal standard, C-10 EO_6. (b) Mass spectra of the C-12 EO oligomers eluted as the single peak 2. As an example, the mass spectrum with $m/z = 473$ is for $[C\text{-}12\,EO_6 + Na]^+$. 2.5 Metals, Metal Complexes and Organometallic Compounds: the Problem of Speciation

Nowadays, probably the most powerful technique for the analysis of metals and organometallic compounds at trace and sub-trace level is ICP/MS. The main features of this technique are the high element specificity, the capabilities of multielement detection, the feasibility of isotopic ratio determinations, the very low detection limits (usually in the low-ppb and ppt range) and the wide linearity range (in most cases up to 5 or 6 orders of magnitude). On the other hand, an inherent limitation of ICP/MS is that it provides only total elemental concentration information, thus denying the speciation and identification of the chemical and organometallic form of the analyte. This fact presents an important drawback in some problems of environmental concern, since the mobility of metals in the environment and their bioavailability depend on their chemical form (free metal, complexed metal, organometallic species). Consequently,

Figure 11 (a) LC/MS chromatogram obtained by injecting 3/100 of the final extract of a tap water sample (4 L). (b) Extracted chromatogram for *m/z* 441, 485, 529, and 573 relative to the most abundant $[M + Na]^+$ adducts of C-16 EO oligomers. Peak numbering is the same as in Figure 10. As measured by this method, the concentrations ($ng\,L^{-1}$) were as follows: NPEOs, 61; C-12 EOs, 10; C-13 EOs, 5.6; C-14 EOs, 5.1; C-15 EOs, 1.7; C-16 EOs, 1.2; and C-18 EOs, 0.5. (c) Mass spectra of the initial part of the chromatogram showing the presence of biointermediates of polyethoxylate surfactants, i.e. PEGs, in the water sample analyzed. As an example, *m/z* 393 is relative to a Na^+ adduct of octaethylene glycol. (Reproduced by permission of American Chemical Society from C. Crescenzi, A. Di Corcia, R. Samperi, A. Marcomini, *Anal. Chem.*, **67**, 1797–1804 © 1995.)

toxicity and environmental impact assessment cannot be adequately observed on the basis of the total concentration of an element.

On-line coupling of LC with ICP/MS permits the elemental detection capabilities of plasma MS to be added to the temporal information for the differentiation of species containing the same element, thus performing speciation analysis.[10] Another advantage of LC/ICP/MS is the possibility of reducing the spectral and non-spectral interferences, which in some cases can represent a severe limitation in the ICP/MS technique. The most commonly used chromatographic mechanisms are IC and IP chromatography; in some cases, the usual RP partition mechanism has been applied and size-exclusion chromatography (SEC) has been proposed for the separation of metals bound to large molecules. The problems due to the chromatographic requirements in LC/ICP/MS have been discussed in section 1.2.

Despite the potential applications, LC/ICP/MS cannot yet be considered a routine technique, owing to the complexity and high costs of the instrumentation and to experimental difficulties, particularly for quantitative analysis; nevertheless, interesting applications to environmental analytical problems have been reported in recent literature (Table 18).[88–94]

An isotope dilution mass spectrometric (IDMS) method has been proposed for the simultaneous determination of the complexes of 11 heavy metals (Ag, Cd, Cu, Mo, Ni, Pb, Tl, U, W, Zn, and Zr) with humic substances (HS).[91] The application of this technique involves the addition to the sample of a known amount of a spike enriched in one of the isotopes of the element under investigation; after mixing of the sample and the spike, the resulting isotope ratio is measured with the mass spectrometer. The use of IDMS for calibration requires that two isotopes of the element to be assayed are free from interference, unless it is possible to correct them. This calibration strategy reduces the influences of short-term fluctuations, long-term drifts and matrix effects on the accuracy of the determination, since isotope ratios instead of absolute responses are used as experimental measurements. Therefore it is particularly suitable for the LC/ICP/MS technique, for which long-term drifts are not negligible owing to the long analysis times. The samples considered were brown water, i.e. natural water characterized by a high content of humic acids, groundwater, sewage and seepage water and a sample of isolated fulvic acids. The total concentrations of the heavy metals and the concentrations of the metal complexes with HS were determined, obtaining detection limits in the 5–110 $ng\,L^{-1}$ range. Figure 12 shows the HPLC/ICP/IDMS chromatograms obtained using SEC and monitoring the signal of copper, zinc and molybdenum respectively, and the corresponding UV absorption profiles of a sewage water sample. The UV curve shows peaks corresponding to different fractions of HS over a broad range of molecular sizes. As it can be seen from the MS profiles, different metals are associated to single HS fractions, indicating specific

Table 18 Selected applications of LC/ICP/MS techniques for the analysis of metals, metal complexes and organometallic compounds in environmental water samples

interactions between each metal and HS of a particular molecular size.

Owing to the widespread presence of chromium and arsenic compounds in the environment via industrial processes, speciation of arsenic and chromium is of particular interest, since the toxicity of these elements greatly depends upon their chemical form. The inorganic arsenic species are highly toxic, whereas the organometallic compounds are less toxic or relatively nontoxic; as for chromium, Cr(VI) is known to be very toxic and carcinogenic, whereas Cr(III) is essential to mammals. IC with ICP/MS detection has been used for the simultaneous analysis of the toxic species Cr(VI), As(III) and As(V) in presence of Cr(III) and organoarsenic compounds.[92] Cr(III) and arsenic species did not interfere with the determination, the former being eliminated before analysis and the latter being separated from inorganic species of arsenic. The separation of Cr(VI) and the arsenic and organoarsenic species arsenobetaine (AB), monomethylarsonic acid (MMA) and dimethylarsonic acid (DMA) is shown in Figure 13. The detection limits (three times the standard deviation of the noise) were $0.5\,\mathrm{mg\,L^{-1}}$ for Cr(VI), As(III) and As(V). The method developed was applied to the analysis of wastewater and drinking water.

LC/ICP/MS has been used for the speciation of the chromium-based azo dyes Acid Blue 193 and Acid Blue 158 reported in Figure 14,[93] with the aim to establish whether the chromium-complex dyes considered are stable in the environment as used, or if they release the metal under real chemical, physical and microbiological conditions. Cr(III) and Cr(VI) were separated on a IC column, whereas the separation of the free and complexed forms of chromium in Acid Blue 193 samples was performed in RP LC. Figure 15 shows the chromatogram of this dye with ICP/MS detection; to avoid the interference of ArC^+ at m/z 52, the signal of chromium at m/z 53 was monitored. The second peak in the chromatogram has the same retention time as that of Cr(III) standard and therefore can be attributed to uncomplexed metal. The chromatogram of Acid Blue 193 obtained under the same conditions, but using UV/VIS detection shows two peaks corresponding to the first and third peaks of the ICP/MS chromatogram; these peaks can thus be assigned to species containing both the metal and the organic species. A third peak, which was not present in the ICP/MS profile, appears in the UV/VIS chromatogram; this indicates that the chromium metal was not incorporated in the dye.

ORGSn represent other analytes of interest from a toxicological point of view. As a consequence of the use of tributyltins (TBTs) and triphenyltins (TPhTs) as antifouling paints for fish nets and ship hulls, a considerable release of these compounds into the aquatic environment occurs. RP IP was the LC mechanism employed for the separation of tri-substituted tins from mono- and di-substituted forms; in particular, the method was developed for the determination of TBT and TPhT in water samples.[94] ICP/MS detection was carried out by monitoring the tin major isotope at m/z 120. Figure 16 shows the IP chromatogram of a triethyl-, triphenyl- and TBT mixture. Since the detection limit achieved with the system used ($200\,\mathrm{ng\,L^{-1}}$) was inadequate for applicative purposes, a preconcentration procedure using C_{18} cartridges was applied on spiked water samples. In such a way, near 100% recoveries were obtained, reaching detection limits of typically $2\,\mathrm{ng\,L^{-1}}$ for both TBT and TPhT.

In addition to HPLC/ICP/MS methods, analytical methodologies based on the use of ES/IS techniques have been proposed for organometal analysis.[95–97] The development of LC/API/MS methods originates from the lack of molecular information on the organometallic species,

which is the main drawback of ICP/MS. A pioneering study on the use of IS/MS/MS in FIA mode for the characterization of organotin species is that of Siu et al.;[95] this technique proved to be extremely sensitive for TBT determination in environmental samples, the minimum detectable amount being 0.2 μg of Sn g^{-1} of sediment. On the other hand, FIA of the organometallic compounds has serious limitations when used for the assay of real sample extracts; using API techniques, the HPLC separation of the analytes is needed to achieve useful information for organometallic speciation in environmental samples. Methods based on the use of LC coupled with API/MS techniques have been applied to the organoarsenic speciation in marine certified reference materials[96] and recently to the organotin speciation in sediments.[97] In this work, a valuable chromatographic method using chromatographic conditions compatible with both APCI/MS and ICP/MS systems has been proposed for the determination of dibutyltin, TBT, diphenyltin and TPhT in sediment samples.[97] The two LC/MS techniques were shown to be useful in providing complementary information about the organotin species present in environmental samples, combining the molecular information of the intact organometallic compounds with the high selectivity and sensitivity of ICP/MS. Using LC/ICP/MS, detectability of the organotin species was approximately 200 pg mL^{-1}, whereas the LC/APCI/MS technique provided higher detection limits, being in the 50–100 ng mL^{-1} range.

3 SAMPLE TREATMENT: OFF-LINE AND ON-LINE PROCEDURES

Every instrumental method requires a chemical preconcentration if it does not fulfill the required limit

Figure 14 Structures of Acid Blue 193 and 158. (Reproduced by permission of Elsevier Science Publishers B.V. from G.K. Zoorob, J.A. Caruso, *J. Chromatogr. A*, **773**, 157–162 © 1997.)

Figure 15 Chromatogram of 50 ng of Acid Blue 193 by RP LC. The mobile phase composition was water–methanol (80 : 20, v/v). The flow-rate was 1 mL min^{-1}. (Reproduced by permission of Elsevier Science Publishers B.V. from G.K. Zoorob, J.A. Caruso, *J. Chromatogr. A*, **773**, 157–162 © 1997.)

of detection. Recently, attention has been paid to the development and application of off-line and on-line preconcentration procedures in environmental analyses. With on-line methods, sample treatment generally involves SPE. The schematic apparatus involving SPE followed by LC/MS is shown in Figure 17. In such systems, the preconcentration of analytes from 50–250 mL water samples is obtained using a small cartridge packed with a

Figure 16 IP chromatogram of triethyltin (A), TPhT (B) and TBT (C) separated on the Kromasil-100 column using a mobile phase of 84% (v/v) methanol, 0.3% (v/v) triethylamine, 2.5% (v/v) acetic acid and 10 mg/100 mL oxalic acid; 100-µL injection of a mixture of 4.81 ng mL^{-1} triethyltin and 4.76 ng mL^{-1} of both triphenyl and TBT as their salts. hydrophobic sorbent and performing subsequent gradient elution of the analytes extracted over an analytical column; detection is usually carried out with a UV DAD or MS. Another approach involves the use of single-column LC systems, in which analyte enrichment and chromatographic separation are performed on one short analytical column; the combination of this fast procedure with MS or MS/MS detection has been demonstrated to be quite promising.[48]

The on-line coupling of sampling treatment with LC/MS techniques represents an important advance in the development of efficient methods of extraction and analysis for organic pollutants from aqueous samples

Figure 17 Schematic representation of the automated on-line SPE/LC/API/MS/MS system. (Reproduced by permission of Elsevier Science Publishers B.V. from J. Slobodník, A.C. Hogenboom, J.J. Vreuls, J.A. Rontree, B.L.M. van Baar, W.M.A. Niessen, U.A.Th. Brinkman, *J. Chromatogr. A*, **741**, 59–74 © 1996.)

at trace levels. Besides sensitivity enhancement, advantages of the on-line approaches are sample throughput increase and automation capabilities, which make the overall LC/MS set-up routine for environmental analysis. Using adequate on-line trace-enrichment procedures, an improvement of analyte detectability of one or two orders of magnitude can be achieved and detection limits at nanogram per liter levels have been obtained for polar pesticides in water samples.[41,43,45,48–50,53] On-line monitoring systems referred to polar pesticides have been extensively discussed in the reviews of Slobodník et al.[27] and of Brouwer et al.[98]

Compared with on-line SPE, off-line SPE is more laborious and time-consuming; in addition, the problems which can be encountered in the application of this procedure are poor recoveries due to analyte losses during the solvent evaporation step. Conversely, because of the ''closed'' nature of an on-line set-up, contamination of the extract during treatment is reduced and losses of the target analytes do not occur. In addition, interferences present in the cartridges or the matrix have to be taken into account during the preconcentration of pollutants from water.

On-line preconcentration techniques have been also applied in LC/ICP/MS analysis of metals and organometallic compounds.[88] Even though ICP/MS is one of the most sensitive detection system for HPLC and generally it does not require trace enrichment, in speciation analysis there is a demand for ever lower detection limits. An off-line sample preconcentration approach has been recently reported for the determination of TBT and TPhT in water,[94] as discussed in section 2.5.

ACKNOWLEDGMENTS

The author gratefully thanks Professor Alessandro Mangia (University of Parma, Parma, Italy) for his valuable discussions and suggestions in the preparation of this manuscript and Dr. Lisa Elviri (University of Parma, Parma, Italy) for technical assistance.

An overview of the applications of photoluminescence techniques for the analysis of polycyclic aromatic compounds (PACs) in environmental samples is presented. The basic experimental procedures of several techniques, such as room-temperature fluorimetry, low-temperature phosphorimetry (LTP), micelle-stabilized room-temperature phosphorimetry (MSRTP), sensitized room-temperature phosphorimetry (RTP), solid-surface room-temperature phosphorimetry (SSRTP), and Shpol'skii spectrometry at 77 K are provided. Analytical figures of merit, such as linear dynamic ranges (LDRs) of calibration curves, limits of detection, and relative standard deviations (RSDs), are compared. Basic spectrofluorimeters for direct laboratory analysis of organic pollutants and instrumental systems utilized for chromatographic detection are discussed. Emphasis to portable devices using laser excitation is given to illustrate the usefulness of photoluminescence techniques for field and remote analysis of contaminated sites. Specific examples of emerging technology developed in the author's laboratory are presented to illustrate recent advances in photoluminescence analysis of environmental samples.

1 INTRODUCTION

Environmental analysis of organic pollutants is mostly performed by chromatographic techniques. The United States Environmental Protection Agency (USEPA) 500 series for drinking water analysis is a representative example.[1] The USEPA 500 series is summarized in Table 1. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) associated with a wide variety of detection techniques are the basis of USEPA methodology. Only three methods (547, 549/549.1, and 550/550.1) use fluorescence detection. The hydrophobic nature of organic pollutants leads to concentration levels below the limit of detection (LOD) of chromatographic methods. Purge-and-trap extraction (PTE), liquid–liquid extraction (LLE) and solid–liquid extraction (SLE) techniques provide preconcentration of organic pollutants. In addition to preconcentrating the sample, extraction techniques simplify matrix composition and facilitate analytical resolution in the chromatographic column.

Although chromatography provides comprehensive methodology for a wide variety of organic pollutants, the assays are tedious, laborious, time-consuming and expensive for routine analysis of numerous samples. Elution times of 30–60 min are typical and standards must be run periodically to verify retention times. If the concentrations of target species are found to lie outside the detector's response range, the sample must be diluted and the process repeated. On the other end of the concentration range, many samples are ''zeroes'', i.e. the concentrations are below the LOD. Problems arise when laboratory procedures are scaled up to handle thousands of samples under mass screening conditions.

Therefore, there is a continuous search for simple and rapid screening techniques that can tell beforehand whether environmental samples merit the full-blown chromatographic procedure. The main trust of luminescence techniques in environmental analysis is to provide screening methodology and field analysis of organic pollutants in a direct way. Field screening techniques lead to a shorter turnaround analysis time and improve the cost effectiveness for environmental monitoring and remediation. Although a small fraction of environmental pollutants are strong luminescence emitters, which provides inherent selectivity to fluorimetry and phosphorimetry, the limited applicability often can be overcome by using derivatization or indirect methods based on effects such as quenching, complexation, enzymatic catalysis, and immunochemical equilibria. For instance, an excellent review on the direct and indirect analysis of pesticides in environmental samples was reported recently.[2]

This article deals specifically with the luminescent techniques and instruments used to monitor and characterize PACs in environmental samples. PACs, which comprise

Table 1 USEPA 500 series: methods for the analysis of organic pollutants in drinking water

Method	Organic pollutants	Method description
501	Trihalomethanes	GC/ECD or GC/PID/ELCD
502.1	Volatile halogenated organic compounds	Purge-and-trap GC
502.2	Volatile organic compounds	Purge-and-trap Capillary GC/PID/ELCD
503.1	Volatile aromatic and unsaturated organic compounds	Purge-and-trap GC
504/504.1	1,2-Dibromoethane; 1,2-dibromo-3-chloro-propane; 1,2,3-trichloropropane	Microextraction and GC
505	Organohalide pesticides and polychlorinated biphenyl products	Microextraction and GC
506	Phthalates and adipate esters	LLE or SLE and GC/PID
507	Nitrogen- and phosphorus-containing pesticides	LLE and GC/NPD
508	Chlorinated pesticides and aroclors	LLE and GC/ECD
508.1/508.A	Chlorinated pesticides, herbicides and organohalides	LSE and GC/ECD
509	Ethylene thiourea	GC/NPD
513	2,3,7,8-Tetrachlorodibenzo-*p*-dioxin	LLE or LSE and GC with high-resolution MS
515.1	Chlorinated acids	GC/ECD
515.2	Chlorinated acids	LSE and GC/ECD
524.1/524.2	Volatile organic compounds	GC/MS
525.1	Organic compounds	LSE and capillary GC/MS
525.2	Semi-volatile organic compounds	LSE and GC/MS
531/531.1	*n*-Methylcarbamoyloximes and *n*-methylcarbamates	HPLC with postcolumn derivatization
547	Glyphosate	HPLC with postcolumn derivatization and fluorescence detection
548	Endothall	Derivatization, LSE, and GC/ECD
548.1	Endothall	GC/MS
549/549.1	Diquat and paraquat	LSE and HPLC with fluorescence detection
550	PAHs	LLE and HPLC with coupled ultraviolet and fluorescence detection
550.1	PAHs	LSE and HPLC with coupled ultraviolet and fluorescence detection
551	Chlorination disinfection by-products and chlorinated solvents	LLE and GC/ECD
552	Haloacetic acids	LLE, derivatization and GC/ECD
552.1	Haloacetic acids and dalapon	Ion-exchange LSE and GC/ECD
553	Benzidines and nitrogen-containing pesticides	LLE or LSE and HPLC with particle beam MS
554	Carbonyl compounds	Derivatization and HPLC
555	Chlorinated acids	HPLC with photodiode array ultraviolet detector

PID, photoionization detector; ELCD, electrolytic conductivity detector; GC, gas chromatography; GC/PID/ELCD, gas chromatography with photoionization and electrolytic conductivity detectors in series; LLE, liquid–liquid extraction; SLE, solid–liquid extraction; NPD, nitrogen–phosphorus detector; LSE, liquid–solid extraction; MS, mass spectrometry; HPLC, high-performance liquid chromatography; PAH, polycyclic aromatic hydrocarbon.

condensed multi-ring benzenoid compounds, are important environmental pollutants originating from a wide variety of natural and anthropogenic sources. Owing to the intrinsically strong fluorescence emission from the rigid π-electron system of PACs, luminescent techniques have been utilized extensively for PAC identification and quantification in environmental samples. The parent homocyclic species, which contain only carbon and hydrogen, are the PAHs. Sixteen PAHs are of extreme environmental concern due to their carcinogenic effect. Their molecular structures are presented in Figure 1. In addition to PAHs, there are thousands of PACs with substituent groups such as alkyl, amino, chloro, cyano, hydroxo, oxy or thio groups. In this review, the term PAC is used to include both heterocyclic and homocyclic compounds, whereas the term PAH is used to designate only homocyclic hydrocarbons.

2 LUMINESCENCE TECHNIQUES

2.1 Fluorimetry

Room-temperature fluorimetry offers the advantages of simplicity, relatively inexpensive instrumentation, calibration curves with LDR over three to four orders of magnitude, and LOD ranging from the picograms per milliliter to the nanograms per milliliter level.[3] In most cases, sample deoxygenation is not necessary and introducing the quartz sample cell into the compartment of a spectrofluorimeter easily performs fluorescence measurements.

A basic spectrofluorimeter for steady-state fluorescence measurements is equipped with a continuous wave (CW) excitation source, which is usually a xenon arc lamp operated at high pressure for continuous radiation between 200 and 800 nm. Excitation wavelengths

Figure 1 Chemical structures of the 16 PAHs listed on the USEPA priority pollutant list.

may be selected with bandpass filters or with an excitation monochromator. The detection system consists of: an emission monochromator, which selects the luminescence wavelength region of interest; the photodetector – usually a photomultiplier tube – which converts the luminescent radiant flux to an electrical signal; and the amplifier-readout system, which amplifies and processes the signal as required and displays it in a convenient fashion. A computer may be interfaced to the spectrofluorimeter for data acquisition and instrumental control.

A spectrofluorimeter with a dual sample–reference measurement capability may be used to compensate for instrumental distortions such as source intensity fluctuations and wavelength dependence, efficiency of the excitation wavelength selector and optical components, and wavelength dependence of detector response. Several accessories are available commercially that can be used to collect corrected excitation spectra. Improvements in signal-to-noise ratio can be obtained by using a photon-counting detection system.

Conventional fluorimetric methods – in which either the excitation or emission wavelength is set at its maximum position while the other is scanned – present limited selectivity. In the analysis of complex mixtures, the similarity and/or overlapping of broad fluorescence bands at room temperature usually interfere in the characterization process of single components. Thus, fixed-wavelength scans often do not provide either quantitative or even qualitative information for many real-world, multicomponent samples.

Several luminescence techniques have been developed to improve the selectivity of luminescence measurements. Warner et al.[4–6] have been pioneers on the use of excitation–emission matrices (EEM), lifetime and polarization measurements, and their simultaneous application to achieve a high degree of selectivity. Additionally, one can take advantage of miscellaneous methods such as quenching effects, surfactant-enhanced luminescence (micelles, etc.), chemical derivatization, and fluorescence detection in chromatographic separations such as thin-layer chromatography (TLC), paper chromatography, and HPLC.

A relatively simple approach for the simultaneous analysis of multicomponent mixtures is the synchronous excitation technique. Originally proposed by Lloyd for spectral fingerprinting of oil samples in forensic analysis, synchronous excitation was later developed by Vo-Dinh et al. for preliminary screening of PACs in environmental samples and for on-site luminescence analysis of PACs.[7–9] This approach consists of varying simultaneously both the excitation (λ_{exc}) and emission (λ_{em}) wavelengths while keeping a constant wavelength interval

$\Delta\lambda(\lambda_{em} - \lambda_{exc})$ between them. The advantages of synchronous excitation include simplification of emission spectra, reduction of the spectral range for a given analyte, and narrowing for spectral bandwidth. Synchronous excitation can be performed with any commercial spectrofluorimeter in which excitation and emission monochromators can be interlocked. Spectral acquisition is performed using narrow excitation and emission slits. Although the use of narrow slits limits the sensitivity of the technique, it avoids undesired scattering and stray light interference resulting from the small $\Delta\lambda$ value.

The use of laser excitation provides several advantages to fluorimetric measurements over commercial spectrofluorimeters. Because the irradiance of a laser is greater than that of a conventional source with typical excitation bandpass values, laser excitation increases the intensity of fluorescence emission. Depending on the behavior of background emission upon laser excitation, an improvement in LOD can be observed. Laser-induced fluorimetry (LIF) has been employed successfully for monitoring trace organic pollutants in a wide variety of environmental samples.[10]

Laser excitation is also advantageous for synchronous luminescence spectroscopy of PACs. Because of the small $\Delta\lambda$ value usually employed in synchronous excitation, the use of large excitation slits with commercial spectrofluorimeters may create scatter and stray light interference. The fluorescence intensity of synchronous spectra, therefore, is usually limited by the use of narrow spectrometer slits. The narrow line width of the laser beam allows one to use small $\Delta\lambda$ values and still achieve high irradiance excitation. LOD at the zeptomole (10^{-21} mol) level has been estimated for several PACs without previous separation from complex matrices.[11,12]

The strong fluorescence signals exhibited by PACs contribute to the popularity of HPLC detectors. The high sensitivity of fluorescence has been augmented by the commercial availability of programmable detectors. These detectors allow the excitation and emission wavelengths to be changed throughout the chromatographic run in order to target compounds during their retention time windows. Commercial spectrofluorimeters can now scan at rates of many hundreds of nanometers per second, which allows on-the-fly spectra collection of chromatographic peaks if a flow cell is used. This type of spectrofluorimeter has been employed to collect full PAH EEM in a variety of water samples.[13,14]

Fluorescence lifetime is another parameter that can be used to distinguish among compounds with overlapping excitation and emission spectra. Because fluorescence lifetime values range from picoseconds to microseconds, their timescale is much faster than the timescale of chromatography. Pulsed laser sources and fast detection systems allow temporal resolution of fluorescence decays during peak elution. McGown et al.[15] have been the most active researchers in this area. On-the-fly fluorescence detection has been applied to the ultratrace-level determination of PAHs in a variety of environmentally related samples.

2.2 Phosphorimetry

Phosphorimetric techniques include solution LTP, MSRTP, sensitized room-temperature phosphorimetry in liquid solution (SRTPL), and SSRTP. The interested reader is referred to comprehensive texts concerning modern phosphorimetric analysis.[16,17]

The first generation of commercial equipment for phosphorimetric measurements consisted of a spectrofluorimeter equipped with a phosphoroscope for time discrimination of short-lived phenomena. Recent spectrofluorimeters are equipped with a pulsed lamp and a gated detection system, which allow collection of phosphorescence lifetimes in the long microsecond to millisecond time domain.

Early work in phosphorimetry was carried out at liquid nitrogen temperature (77 K). By using cryogenic equipment, the solutions were frozen to a rigid matrix to minimize the collisions competing with phosphorescence for deactivation of the triplet state. Because of the long lifetime of the triplet state, careful sample deoxygenation is recommended to avoid quenching of phosphorescence intensity. Sample deoxygenation prior to phosphorescence measurement can be accomplished by purging pure nitrogen gas through the sample solution. The main advantages of LTP are low LOD (nanomolar ranges), calibration curves with wide LDR (10^4 to 10^6-fold change in analyte concentrations) and narrow phosphorescence bands that enhance selectivity.[18] However, very little LTP research has been done in recent years. The lack of widespread use is mainly attributed to three reasons: the high cost of cryogenic equipment; the time-consuming sample deoxygenation; and the poor reproducibility of measurements. Although a skilled technician can obtain a RSD lower than 5%, it is not unusual to obtain RSD values as high as 20%.

Cline-Love et al.[19,20] first applied MSRTP in aqueous solution as an analytical method. The method was employed to determine a wide variety of compounds, including ketones, aldehydes, alcohols, carboxylic acids, phenols, and amines. Organized media stabilization was made with the use of sodium dodecyl sulfate micelles in the presence of thallium(I) or silver(I) as a phosphorescence enhancer. Micellar solutions are colloidal aggregates or detergents that incorporate analyte molecules in their micelle cavity to protect the triplet state from collisional and vibrational deactivation. The aggregation of surfactants only occurs above a certain

concentration, known as the critical micelle concentration (CMC). This concentration depends upon the chemical structure of the surfactant and the nature of the solvent. If no data on CMC values are available in the literature, the CMC of a particular surfactant–solvent system can be determined by fluorescence titration of a probe compound,[19,20] capillary electrophoresis,[21–23] or microcalorimetric titration.[24] The use of microemulsions as organized media has also been proposed to enhance RTP emission of PAHs and pesticides in liquid solutions.[25,26] Cline-Love et al. reported on the use of different cyclodextrin-stabilized RTP methods using β-cyclodextrin.[27–29]

The main disadvantage of MSRTP is the necessity of thorough sample deoxygenation, which results in analysis times of approximately 1 h. Shorter analysis times can be obtained by using sodium sulfide as oxygen scavenger.[30] There are, however, considerable advantages in the use of the micelle method. In most cases, the LOD and precision of MSRTP are similar to those obtained by LTP. The RTP analysis of PACs is facilitated by the high solubility of these species in the micellar environment. Finally, the micelle approach offers a means to conduct phosphorescence analysis in flow systems and liquid chromatography.[16,17]

RTP detection in continuous flows and chromatographic systems can be performed also by means of SRTPL.[31,32] In this technique, the weakly phosphorescent or nonphosphorescent analyte (donor) transfers its triplet energy to a given acceptor. A suitable acceptor should have a triplet energy lower than that of the donor, a high quantum phosphorescence yield, and a lower molar absorption in the excitation region of the donor. In addition, the energy gap between the triplet states of the donor and the acceptor should be enough to prevent significant reverse mechanisms. For instance, biacetyl has shown to be an appropriate acceptor for the analysis of polyhalogenated naphthalenes, dibenzofurans and polychlorinated biphenyls. As a detection technique in flow injection analysis and HPLC, SRTPL obtained LOD in the nanomolar range. In addition to competitive LOD, several advantages justify the use of SRTPL. Because it is an emission technique, SRTPL is inherently more sensitive than ultraviolet absorption. The background due to scattering and fluorescence impurities is negligible at the emission wavelength of biacetyl (522 nm), and it is particularly selective because most sample constituents do not promote the sensitized phosphorescence signal of the acceptor. Further research, however, is necessary to develop new acceptor–donor systems in order to expand the analytical potential of SRTPL.

In the early 1970s, Schulman and Walling[33] reported the observation of strong RTP from a wide variety of ionic compounds adsorbed on solid substrates. Silica, alumina, paper, asbestos, and glass fiber were employed to restrict vibrational and collisional deactivation of the triplet state. Following these early reports, and certainly attracted by the simplicity of the sample procedure, a considerable number of studies on SSRTP have been reported.[16,17]

The classic SSRTP procedure includes two steps: co-spotting microliters of sample and phosphorescence enhancers on the solid substrate with a microsyringe; and drying the sample in an oven (or under an infrared lamp) to minimize water quenching of phosphorescence emission. As with any other analytical method, a satisfactory LOD is obtained with low background signals. The main contribution to background emission in SSRTP is given by the solid substrate. Many materials have been searched to find a substrate with low phosphorescence emission between 350 and 650 nm, which is the spectral region where most compounds phosphoresce. These include filter paper, silica gel, and various combinations of sodium acetate, poly(acrylic acid) and cyclodextrin with sodium halides. Among the materials investigated, filter paper has been shown to be a good, general SSRTP substrate. Its main advantages are low cost, simplicity of handling, and availability of a wide selection of papers, which enable one to select the best substrate for specific phosphors. On the other hand, filter paper presents broad, featureless bands of excitation spectra from 200 to 400 nm, and phosphorescence spectra from 375 to 625 nm. Several attempts have been made to decrease this signal, to some extent, using solvent extraction or chromatography, chemical or heat treatment, or signal background with the help of a computer-assisted spectrophosphorimeter.[16,17] However, the most significant reductions – which were above 90% of the original signal – were obtained with ultraviolet irradiation[34] or a combination of water Soxhlet extraction and ultraviolet irradiation.[35] Because the low background signal remains constant after treatment, batches of treated paper can be stored in a desiccator to be used in routine analysis.

Depending on the PAC and the phosphorescence enhancer, calibration curves with a 10^2–10^3-fold change in the LDR of the analyte concentration, absolute LOD in the nanogram to subnanogram level, and RSD from 5 to 15% can be obtained with a relatively simple procedure. In certain cases, the sensitivity of SSRTP has been improved with matrix-modifier substrates. Diethylene triaminepentaacetic acid, cyclodextrin, and sodium dodecyl sulfate are just three of the many compounds used to modify the surface of filter paper and enhance the enhancing efficiency of heavy atoms and/or PAC RTP emission.[36–38]

If the monitoring of targeted components in complex matrices is of interest, selective external heavy-atom perturbation (SEHAP),[39] second-derivative methods,[40]

and synchronous excitation[7] techniques can be employed to reach specific compound identification. SEHAP, which was first developed by Vo-Dinh and Hooyman,[39] is based on the appropriate choice of a heavy atom salt, which enhances the RTP emission of the target PAC and causes phosphorescence quenching of potential phosphorescent concomitants.

Although these alternatives improve the selectivity of SSRTP, separation prior to RTP detection is convenient when dealing with complex matrices. Paper chromatography and TLC have been proposed as separation techniques for SSRTP.[41,42] The possibility of complete analysis (separation and detection) on the same solid substrate, and the use of RTP spectral characteristics as additional parameters for compound identification, turn paper chromatography/SSRTP and thin-layer chromatography/solid-surface room-temperature phosphorimetry (TLC/SSRTP) into attractive screening tools.

SSRTP has been employed also as a detection technique for HPLC. The chromatographic fractions can be collected manually and spotted onto a RTP substrate,[16,17] or they can be analyzed with an SSRTP automated system that completely eliminates any manual steps.[43,44] In both cases it is possible to characterize single components in partially resolved mixtures, which simplifies the separation process in the chromatographic column. In addition to luminescent parameters such as excitation and emission wavelengths, excited-state lifetimes, synchronous excitation, and second-derivative methods, SEHAP – which is unique to SSRTP – can be used to enhance the selectivity toward a specific component. The combination of these parameters, associated with chromatographic retention times, is certainly valuable for qualitative purposes and for the simplification of chromatographic separation of complex samples.

Very few attempts have been made to improve the detection levels of PACs by laser-induced SSRTP.[45,46] When compared with the absolute LOD obtained with commercial spectrofluorimeters, laser-induced SSRTP provides an improvement of approximately 1000-fold. This improvement results from the high irradiance of the laser source and the small area of solid substrate probed by the laser beam. It is possible to measure nanoliter volumes of sample with good reproducibility. Within the LDR of the studied PAC, the RSD values varied from 7% to 9.5%. The RSD obtained with a commercial spectrofluorimeter[45] for the same analyte mass on the paper substrate varied from 30 to 40%. Even when small excitation slits were employed (10 nm), the irradiated area on the paper substrate excited the analyte signal and the background emission of the solid substrate. Smaller excitation slits (5 nm) resulted in unacceptable analyte-to-background signal ratios. By focusing the laser beam exclusively on the sample spot, it was possible to achieve selective excitation of the analyte, thus avoiding the excitation of background impurities. The low absolute LOD obtained by laser-induced SSRTP simplified soil sample preparation procedures. Because the evaporation of extracting solvent was not necessary to preconcentrate the sample, the direct deposition of nanoliter volumes of organic extract on the solid substrate was sufficient to determine PACs at the nanogram to picogram level.[46]

2.3 Shpol'skii Spectrometry

Shpol'skii spectrometry is part of a group of high-resolution luminescence techniques that include fluorescence line narrowing,[47] matrix isolation,[48] and supersonic jet spectrometry.[49] Because fluorescence line narrowing and matrix isolation can be considered complementary to Shpol'skii spectrometry, and supersonic jet spectrometry has received very little attention in current analytical literature, this review will give an overview of the application of Shpol'skii spectrometry to environmental analysis.

As mentioned previously, common room-temperature fluorescence and phosphorescence spectra of PAHs in solution show broad excitation and emission bands with typical full width at half-maximum (fwhm), values of the order of 300 cm^{-1}. When PAHs are incorporated in a crystalline or polycrystalline matrix (formed at 77 K or below, using appropriate organic solvents), their excitation and luminescent spectra (fluorescence and/or phosphorescence) exhibit fine structure with sharp line (quasi-line) widths (fwhm = 1–10 cm^{-1}). Under the Shpol'skii conditions, the influence of solution inhomogeneity on the luminescence spectra of PAHs is strongly reduced by isolating the guest molecule (analyte) in a host matrix (usually *n*-alkanes) under low (nitrogen or helium) temperature. As a result of the highly structured orientation of solute molecules in the solid solvent, vibrationally resolved excitation and emission spectra, favorable for fingerprinting identification, can be observed. Excellent reviews have discussed the fundamental and applied aspects of Shpol'skii spectrometry.[50,51] These include comprehensive tabulations listing the optimum solvent(s) for observing quasi-line spectra of PAHs, instrumentation, types of environmental samples, and procedures for sample cooling.

Early work in Shpol'skii spectrometry was carried out with excitation sources such as mercury-vapor discharge lamps or xenon lamps. Selection of excitation wavelength was performed with wide-band filters, interference filters, or monochromators. In recent years, the use of pump lasers and dye lasers for sample excitation has dominated the area of Shpol'skii spectrometry. Fassel et al.[52–55] examined extensively the utilization of a tunable dye laser with the Shpol'skii technique for the analyses of PAHs

at 15–20 K in solvent-refined coal and shale oil samples. The merger of quasi-linear absorption spectra with sharp-line laser excitation sources resulted in high selectivity. This technique, which was called laser-excited Shpol'skii spectrometry (LESS), has been employed for selective identification of nitrogen-, oxygen-, and sulfur-containing PACs[56] and isomeric PAHs.[57]

Despite the ability of Shpol'skii spectrometry and/or LESS to provide direct identification of PAHs and PACs in crude extracts of environmental samples, their analytical potentials are still scarcely employed in chemical analysis. From the point of view of quantitative analysis, there are some critical parameters such as the freezing rate, analyte concentration, final temperature, and the necessity of working with an appropriate Shpol'skii solvent that affect the signal intensity (and bandwidth) and, consequently, the analytical results. Other problems include the limited LDR of the calibration curves and the strong scatter observed. According to Fassel and D'Silva,[55] signal reproducibility can be solved by using a careful and reproducible freezing rate and a low analyte concentration (10^{-6} M or lower). The scatter is not a problem if the excitation wavelength is at least 10 nm lower than the emission wavelength, and the matrix compatibility is not an issue because *n*-heptane can be used with several PAHs with three- to six-ring structures. To compensate for the inner filter effect or enhancement effects, the standard addition and the internal standard method can be employed.

However, one of the main problems associated with the lack of analytical use of Shpol'skii spectrometry is the impractical sampling procedure. Two types of sampling systems are commonly used. For a temperature of 77 K, the sample is introduced into a glass or quartz tube followed by direct immersion into a Dewar flask with liquid nitrogen. The drawbacks are several, beginning with the somewhat fragile Dewar vessel. Small ice particles in the liquid nitrogen act as nucleation sites, which cause bubbling at irregular intervals and disruption of the optical path. Condensation on the outside of the Dewar flask similarly degrades the quality of the spectra. The excitation and emission light must pass through many airglass and other interfaces that scatter the exciting light, and the snowy Shpol'skii matrix is also strongly scattering. As a result of the irreproducibility from sample to sample, a RSD as high as 15–20% can be obtained. For temperatures below 15 K, cryostats or closed-cycle refrigerators are used, where the coolant can be liquid helium. However, helium closed-cycle refrigerators, Joule–Thomson miniature refrigerators, cryostats that cool the sample in cold vapor, contact cooling, etc. lack the simplicity of ''dunking'' the sample into liquid nitrogen.

3 FIELD MONITORING IN ENVIRONMENTAL ANALYSIS

The high coupling efficiency of lasers to fiber optics is useful in remote sensing applications. LIF with optical fibers has been used to monitor PACs in environmental samples.[58–62] The specificity of LIF sensors can be improved by coating selective receptors at the distal end of the fiber optic. For instance, a highly selective detector has been reported for pyrene and other PAHs that use β-cyclodextrin as a selective receptor.[58] Its high selectivity toward PAHs results from the hydrophobic nature of the β-cyclodextrin tip, which does not complex with other heterocyclic concomitants in contaminated water samples. Similarly to fluorescence measurements in solution, spectral overlapping of fluorescence species can be improved by temporal resolution.[59–62]

A remote fiber-optic sensor has been developed to detect PAHs on a real-time basis.[63] The device, which uses a pulsed nitrogen laser as excitation source and a gated charge-coupled device (CCD) detector at the focal plane of a spectrograph, is able to detect anthracene at nanogram per milliliter levels in 10 μs. Another instrumental system that can be used with standard cuvette sample holders or fiber-optic probes was developed recently to monitor PACs in environmental samples.[11] It is based on laser-induced synchronous luminescence and allows several laser dyes to be used in a single scan (multidye scan), which extends the wavelength excitation range. When the laser wavelength reaches the edge of the lasing region of one dye, the computer control program pauses for a few seconds to allow manual insertion of a new dye solution. The dye exchanging process is rapid and simple because no optical realignment is necessary. The wavelength regions scanned by different laser dyes in a multidye scan need not be continuous and different $\Delta\lambda$ values can be used. By using the fiber-optic approach, benzo[*a*]pyrene and perylene were detected at the parts-per-billion ($ng\,mL^{-1}$) level in a water sample.

A SSRTP fiber-optic probe has been developed recently for the analysis of PACs in contaminated waters.[64,65] A pulsed nitrogen laser and a dye laser were used as excitation sources. At the tip of a bifurcated fiber-optic bundle, the RTP probe, which consisted of a cavity between two cylindrical parts attached by concentric incised threads, provides the paper substrate compartment. A hole at the distal end of the probe allows the entry of water into the substrate cavity. By dipping the probe into the water sample, the paper substrate is imbibed with water, which is retained on the solid substrate. RTP measurement is performed after removing the probe from the water sample and drying the substrate under an infrared lamp. Several PAHs and nitrogen

heterocyclic compounds of environmental importance were determined at the parts-per-billion level.[64,65]

Although the SSRTP probe does not allow in situ analysis of water samples, fiber-optic sensing based on phosphorescence emission offers higher selectivity over fluorescence optosensing. The higher selectivity is based on the fact that phosphorescence is less common than fluorescence at room temperature. The interference from short-lived scattering and possible fluorescence signals can be avoided by using appropriate delay times after the excitation pulse. This is particularly useful in reducing or even eliminating the spectral interference of humic and fulvic acids, a problem usually encountered with fluorescence optosensing of PACs.[58–62] SEHAP can provide enhanced selectivity for the direct determination of a target compound in complex mixtures with several luminescent (fluorescent and/or phosphorescent) compounds. Other advantages include the use of low-cost optical fibers (phosphorescence occurs at emission wavelengths longer than 450 nm) and relatively-low-cost instrumentation for time-resolved measurements, because triplet-excited lifetimes are in the millisecond (or higher) time domain and, therefore, they are easier to resolve instrumentally than fluorescence lifetimes.

The RTP probe presents unique features for field analysis. Its design minimizes contact between the sample and quenching species such as oxygen and atmospheric humidity. By using appropriate heavy-atom salts, the excitation wavelengths of the compounds of interest can be shifted to overlap the excitation line of the laser source and avoid the change in excitation source. By spotting standard solutions on the paper substrate imbibed with the sample, on-site identification and determination of compounds can be performed. By changing the paper substrate in the sample compartment, the RTP probe can be used for an infinite number of measurements, which reduces analysis time and cost when compared to coated fiber-optic sensors.

4 NEW TRENDS IN LUMINESCENCE ANALYSIS OF ENVIRONMENTAL SAMPLES

SLE is nowadays the recommended method for the sample pretreatment of complex matrices, and the use of LLE has dropped dramatically following obligatory reduction of chlorinated solvent usage in analytical laboratories. In water analysis, SLE concentrates the organic pollutants by sorption onto an octadecyl (C_{18}) organic phase chemically bonded to silica particles. When compared to LLE, SLE reduces solvent consumption, has fewer steps, saves labor, provides better extracting efficiency, prevents emulsions, enables easy sample collection, and is more amenable to automation.[66]

SLE, however, presents certain disadvantages for chromatographic analysis. The mechanism of isolation on C_{18} membranes is van der Waals' forces (also called nonpolar, hydrophobic or reversed-phase interactions) and occasionally secondary interactions such as hydrogen bonding and dipole–dipole interactions. Nonreversed-phase interactions (hydrogen bonding and dipole–dipole interactions) result from unreacted (residual) silanol and siloxane groups on the surface of octadecyl silica phases. These interactions are stronger than van der Waals' forces and can cause poor analyte recovery. An additional consideration for efficient analyte elution is the removal of water from the C_{18} sorbent. In order for the elution solvent to wet effectively the bed of the sorbent, it is necessary to remove the water in the void volume, trapped water, and water sorbed to the silica. Air or a vacuum may be used to remove the majority of the water in the void volume. The water in the smallest pores and water that is sorbed to the silica surface will be tightly trapped or bound to the silica surface. The bound water may be removed by drying the sorbent under a vacuum (25 mmHg) for at least 15 min. Another approach is to use an eluting solvent that is miscible with water. For instance, a mixture of methylene chloride–ethyl acetate (1 : 1) gives recoveries of 85–95% for the 46 pollutants listed in the USEPA method 525.1.[1] Methylene chloride, on the other hand, gives low analyte recoveries (40–70%). These low recoveries most likely arise from the inability of methylene chloride to displace and penetrate the water saturating the internal pores of the silica phase. Finally, a source of potential contamination in SLE is the presence of impurities in the cartridge or disk (such as phthalate esters) that leach from the adsorbing material into ethyl acetate and methylene chloride and produce a variable background in the water sample.

A new approach for screening PACs in water samples is being developed in our laboratory.[67–69] The new analytical tool combines SLE with SSRTP. Because the analysis of PACs is performed on the adsorbing material, the drawbacks associated with SLE procedures are eliminated. The ability of SSRTP to measure nanogram to subnanogram levels of PACs on the extraction membrane allows one to use relatively small water sample volumes. This is advantageous because it simplifies the extraction procedure and reduces analysis time. Figure 2 shows the apparatus employed for 10-mL SLE of water samples. Conventional water SLE procedures, which rely on processing 1 L of water through the extraction membrane, require bulky glassware, a vacuum pump, an oven to dry the sample following water extraction, and relatively long analysis times (~1 h per sample).

Figure 2 SLE apparatus and sample preparation procedure for RTP analysis. SDS, sodium dodecyl sulfate.

By using syringes and stainless-steel filter holders, the bulky glassware and vacuum pump are removed from the extraction procedure. The oven-drying step is substituted by air sample drying, which employs positive pressure to remove water excess from the extraction syringe. As a result, analysis times of 3–5 min per sample are obtained, which are extremely attractive for screening large number of samples. The LOD values for the 16 PAHs of the USEPA priority list (see Figure 1) were estimated with a commercial spectrofluorimeter at the picogram per milliliter level. LOD values at the parts-per-trillion level were also estimated for polychlorinated biphenyls and dibenzofurans. Selective identification of total PAHs, polychlorinated biphenyls and dibenzofurans was obtained by appropriate selection of heavy-atom salt and delay and gate times. Although further studies are necessary to prove solid–liquid extraction/room-temperature phosphorimetry (SLE/RTP) as a reliable analytical tool, the simplicity of the new experimental procedure, the analytical figures of merit and the selectivity of SLE/RTP show its analytical potential for initial screening of numerous water samples.

A similar approach is being developed by Hurtubise et al.[70,71] at the University of Wyoming (WI, USA). Whatman 1PS filter paper is used as the solid-phase microextraction medium for PAHs in water. This filter paper is based on the same cellulose substrate as Whatman no. 1, but it is impregnated with silicone oil in the presence of an organotin catalyst. It is believed that the tin remaining in the coating may act as a heavy atom, facilitating the acquisition of RTP spectra. The silicone provides a hydrophobic surface onto which PAHs can be extracted from water. The PAHs on the surface of the Whatman 1PS paper are detected at the nanogram per milliliter level by using fluorescence and/or phosphorescence measurements.

A fiber-optic probe was employed recently in our laboratory to test a new sampling procedure for photoluminescence measurements at 77 K. The probe consisted of one excitation fiber surrounded by six emission fibers. The launch and collection fibers were bundled with vacuum epoxy. Figure 3 shows a schematic diagram of the fiber-optic probe and measuring procedure. A 1-mL aliquot of sample solution was introduced into a 5-mL Pyrex test tube, and the test tube was then introduced into a container with liquid nitrogen. Figure 4 shows the instrumental system used with the fiber-optic probe. The intensifier in front of the CCD chip acts as a super-fast shutter, capable of operating on a nanosecond timescale. The parameters for data acquisition (gate delay, gate width, and the gate step) are entered in a computer, using

Figure 3 Fiber-optic probe for photoluminescence measurements in Shpol'skii matrices.

Figure 4 Instrumental system for laser-excited time-resolved EEM. 1 = doubling crystal; 2 = short-pass filter; 3 = focusing lens; 4 = density filter; I/O = input–output; ICCD = intensified charge-coupled device.

appropriate software. The software sends these intensifier set-up details via a general purpose interface bus (GPIB) interface to the pulse generator. Once triggered by the laser, the pulse generator uses this information to determine when the image intensifier in the detector head is gated on (gate delay), for how long it is gated on (gate width), and the duration of the steps by which the gate delay is progressively increased in the course of the sequence of acquisitions (gate step). The intensifier is gated on for the duration of the pulse, allowing the CCD to acquire data. When the intensifier is gated off, the acquired data are transferred from the detector head to the controller card (32-bit Intelligent Bus-Mastering PCI card) in the computer. With this instrument, it is possible to collect wavelength–time matrices in a few nanoseconds. The entire sample procedure – which includes sample freezing, spectra collection, and probe rinsing for the following measurement – takes less than 5 min, which is extremely attractive for routine screening. Because the fiber-optic probe eliminates scattering surfaces between sample excitation and fluorescence collection, the RSD for several PAHs was excellent, varying from 2% (pyrene) to 7% (phenanthrene). Table 2 shows the LDR and LOD obtained with the new system using optimum delay and gate times. The appropriate choice of delay and gate times for each PAH was based on the analyte and background fluorescence lifetimes. Compounds with long lifetimes, such as pyrene, allow the collection of strong PAH fluorescence emission at delay times where background contribution is negligible (approximately equal to instrumental noise). On the other hand, for a PAH such as chrysene, the complete time resolution of background emission is limited by the short fluorescence decay of the PAH. Therefore, the choice of a delay time for the best analyte-to-background signal ratio involves a compromise between the relative intensities of analyte and background signals.

In addition to the improvement in analyte-to-background signal ratios, time resolution enhances the selectivity of LESS toward the target PAH. Figure 5 shows the fluorescence spectrum of benzo[*a*]pyrene recorded from a standard solution in *n*-heptane. Figure 6 shows the low-temperature fluorescence spectrum of a small volume of oil sample spiked into *n*-heptane. By selecting the delay (10 ns) and gate (50 ns) times based on the fluorescence lifetime of benzo[*a*]pyrene (39.9 ns), it was possible to identify the target PAH in a direct way.

Several separation techniques have been coupled to Shpol'skii spectrometry for the analysis of PAHs in "real world" samples. In the specific case of water

Figure 5 Low-temperature fluorescence spectrum of benzo[*a*]-pyrene in *n*-heptane.

Figure 6 Low-temperature fluorescence spectrum of a contaminated oil sample spiked into *n*-heptane.

Table 2 LDRs and limits of detection obtained by LESS using a fiber-optic probe and a time-resolved EEM instrument

Analyte[a]	$\lambda_{exc}/\lambda_{em}$[b] (nm)	LDR[c]	LOD[d] (ng mL^{-1})
Pyrene	280/384	6×10^4	0.5
Phenanthrene	287/365	1.7×10^3	12
1,2 : 5,6-Dibenzanthracene	290/394	1.7×10^4	0.06
Chrysene	286/381	2.8×10^2	0.7
Benzo[*g*,*h*,*i*]perylene	290/421	6.7×10^3	0.2
Naphthalene	282/323	7.5×10^3	0.8

[a] Analyte solutions were prepared in *n*-heptane.
[b] Excitation and emission wavelengths. Emission wavelengths correspond to maximum emission wavelengths.
[c] LDR is calculated by dividing the upper linear concentration by the LOD.
[d] LOD is calculated based on the equation LOD = $3S_b/m$, where S_b is the standard deviation of 16 blank measurements and m is the slope of the calibration curve.

Table 3 Limits of detection estimated by SLE and LESS

Analyte[a]	$\lambda_{exc}/\lambda_{em}$[b] (nm)	LOD[c] (pg mL^{-1})
Pyrene	280/384	0.09
Benzo[*a*]pyrene	290/410	0.2
Chrysene	286/381	0.6
Fluoranthene	290/438	34

[a] Analyte solutions were prepared in *n*-heptane.
[b] Excitation and emission wavelengths. Emission wavelengths correspond to maximum emission wavelengths.
[c] LOD is calculated based on the equation LOD = $3S_b/m$, where S_b is the standard deviation of 16 blank measurements and m is the slope of the calibration curve.

sample preparation, LLE has been the approach used the most.[50] In addition to the previously discussed advantages of SLE over LLE, the combination of SLE with LESS presents a unique feature, which is obtained if the eluting and the Shpol'skii solvent are the same. A three-step sample procedure (extraction, elution, and fluorescence measurement) then is obtained, which provides a quick and simple method of analysis. Table 3 shows the LOD for several compounds obtained by SLE coupled with LESS. The preconcentration factors achieved by SLE, associated with the small volume of organic solvent used for PAH elution and fluorescence measurement, result in LOD at the femtogram per milliliter level. These values compare favorably with those obtained by room-temperature fluorimetry, where several factors such as lack of scatter, large excited sample volume, spectral bandwidth, and depth of excitation contribute to very low detection levels.[3]

5 FINAL REMARKS

The monitoring and characterization of PACs in complex environmental samples require a battery of analytical methods and instrumentation. Laboratory analysis of PACs is mostly performed by GC and HPLC, which can provide complete characterization of complex matrices after sample clean-up and preconcentration. Because chemical analysis is increasingly moving from the traditional laboratory setting toward in situ applications, analytical chemistry faces the challenge of developing the tools for on-line and field monitoring in real-time bases.

Photoluminescence is inherently a multiparameter phenomenon. The examples presented in this review demonstrate the main thrust of photoluminescence in environmental analysis, which is obviously related to the uniqueness of its multidimensional nature. The measurement of fluorescence and/or phosphorescence from a sample involves the simultaneous use of excitation and emission wavelengths and luminescence lifetimes. The appropriate combination of these parameters, sometimes associated with polarization measurements, chemical derivatization, and/or measurement of effects such as quenching, enzymatic catalysis, and immunochemical equilibrium, provides highly selective and sensitive techniques. To measure the various luminescent parameters and explore the full potential of photoluminescence techniques, the analyst should use a combination of commercial spectrofluorimeters and instrumental set-ups with laser excitation sources, fiber optics, monochromators and spectrographs, photodetectors, and imaging systems. The continuous development of luminescent techniques and instrumentation, associated with the parallel development of novel computer algorithms for reduction and interpretation of large data sets, provides a valuable number of spectrochemical tools for direct laboratory determination of PACs and remote sensing under field conditions.

ABBREVIATIONS AND ACRONYMS

CCD	Charge-coupled Device
CMC	Critical Micelle Concentration
CW	Continuous Wave
EEM	Excitation–Emission Matrix
fwhm	Full Width at Half-maximum
GC	Gas Chromatography
GPIB	General Purpose Interface Bus
HPLC	High-performance Liquid Chromatography
LDR	Linear Dynamic Range
LESS	Laser-excited Shpol'skii Spectrometry
LIF	Laser-induced Fluorimetry
LLE	Liquid–Liquid Extraction
LOD	Limit of Detection
LTP	Low-temperature Phosphorimetry
MSRTP	Micelle-stabilized Room-temperature Phosphorimetry
PAC	Polycyclic Aromatic Compound
PAH	Polycyclic Aromatic Hydrocarbon
PTE	Purge-and-trap Extraction
RSD	Relative Standard Deviation
RTP	Room-temperature Phosphorimetry
SEHAP	Selective External Heavy-atom Perturbation
SLE	Solid–Liquid Extraction
SLE/RTP	Solid–Liquid Extraction/Room-temperature Phosphorimetry
SRTPL	Sensitized Room-temperature Phosphorimetry in Liquid Solution
SSRTP	Solid-surface Room-temperature Phosphorimetry
TLC	Thin-layer Chromatography

TLC/SSRTP	Thin-layer Chromatography/Solid-surface Room-temperature Phosphorimetry
USEPA	United States Environmental Protection Agency

The accurate, precise, and automated determination of mercury in biological and environmental samples is complex, not only because of the various oxidation states of mercury (i.e. 0, I and II), but also because of biotic and abiotic methylation and the volatility of several forms of mercury(I and II). Mercury is unique among the metals because of its large vapor pressure at ambient conditions. Mercuric ions in solution can be reduced by tin(II), or sodium borohydride to produce volatile elemental mercury, referred to as the cold vapor process. The mercury is swept out of solution with a carrier gas (in the gas of sodium borohydride, the byproduct is hydrogen) into the cell (or torch) where the atomic absorption (or fluorescence, or emission) is measured. The cold vapor technique removes the mercury from the sample matrix, concentrates the mercury in the analytical sample into a small plug of carrier gas, and provides for a relatively long residence time. Detection limits vary depending on the instrument but are in the submicrogram to nanogram per liter range for atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS), and inductively coupled plasma atomic emission spectrometry (ICPAES).

1 INTRODUCTION

A naturally occurring element, mercury's unique properties have been valued for several centuries. The metal cycles in the environment as a result of natural and anthropogenic activities. Mercury in most environmental matrices occurs at low concentrations; therefore, sensitive analytical methods are necessary for its detection. Mercury is a known toxicant, and is known to bioaccumulate especially in the aquatic food web. In the 1950s and 1960s two major epidemics of methylmercury poisoning through fish consumption occurred in Minamata Bay and Niigata (both in Japan), where thousands of people were affected. Environmental monitoring of mercury is meaningful. Due to the complexity of mercury biogeochemical cycling, monitoring of mercury requires the analysis of many different matrix types, such as air, waters, soils, sediments, sludges, as well as range of biological matrices. Mercury determination is complicated by the multiple oxidation states of naturally occurring mercury but also because of biotic and abiotic methylation and the volatility of several forms of mercury.

Typically, samples are decomposed in the presence of acid(s) and oxidizing agents (which are necessary to prevent volatilization of mercury). The excess oxidizing agent is then prereduced under mild conditions. The samples are then ready for cold vapor analysis, in which a strong reducing agent, such as tin(II) or sodium borohydride, is added to reduce the mercury to the volatile elemental form. In the case of AAS, the mercury is swept from the system by an inert gas into the cell where the absorption is measured. Similar designs are used for AFS and for ICPAES. The cold vapor technique removes mercury from the liquid matrix, reducing interferences.

R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

In addition, the technique concentrates all the mercury from the entire sample into a small plug within the carrier gas. Sample sizes as large as 50 mL are routinely used; mercury from the entire 50 mL is purged out as volatile mercury, and aspirated into an AAS, AFS, or ICPAES instrument. This represents a huge increase in sample size as compared to typical aspiration sample delivery. This process is referred to as the cold vapor mercury analysis technique. The sensitivity is several orders of magnitude better than for conventional AAS, AFS, or ICPAES analysis.

2 CHEMISTRY

2.1 Properties of Mercury

The heavy metal mercury (Hg), atomic number 80 and atomic weight 200.59, is a silver-white heavy liquid at typical ambient temperatures and pressures (specific gravity 13.5 $kg\,L^{-1}$ CAS 7439-97-6). Mercury's melting point is −38.89 °C and boiling point (bp) is 357.25 °C under atmospheric pressure. Mercury is the only metal which is a liquid at room temperature. The reason for this is that mercury has a very high ionization energy (first ionization potential = 1007 $kJ\,mol^{-1}$)[1] which makes it difficult for electrons to participate in metallic bonding. Mercury metal has a high vapor pressure (0.16 Pa at 20 °C), and vaporizes readily under ambient conditions; a saturated atmosphere would contain approximately 15 $mg\,Hg\,m^{-3}$ at 20 °C.[2]

Elemental mercury dissolves numerous other metals (gold, silver, platinum, uranium, copper, lead, sodium, and potassium) to alloys, called amalgams. Mercury is unusual among metals because it tends to form covalent bonds rather than ionic bonds.

2.2 Properties of Mercury Compounds

Mercury can exist in three oxidation states: Hg^0 (metallic), Hg_2^{2+} (mercurous), and Hg^{2+} (mercuric), equivalently designated as Hg^0, Hg^I and Hg^{II}. The properties and chemical reactivity of mercury strongly depend on the oxidation state. Mercurous and mercuric mercury form numerous inorganic and organic chemical compounds; however, mercurous mercury is rarely stable under typical environmental conditions. Only a few mercurous compounds are known; mercury(I) is unique in that these compounds contain the mercurous ion $(Hg{-}Hg)^{2+}$, not Hg^+. However, halides of mercurous mercury form readily, and Hg_2Cl_2 is used extensively in chemical applications (often referred to by its trivial name, calomel).

Most mercury in the environment, including waters, soils, sediments and biota, occurs in the forms of inorganic mercuric salts and organomercurics. Organomercurics are defined by the presence of a covalent Hg−C bond. The mercury compounds most likely to be found in the environment (atmospheric mercury being the exception) include the following: mercuric salts, for example $HgCl_2$, $Hg(OH)_2$, and HgS, methylmercury compounds, for example methylmercuric chloride (CH_3HgCl) and methylmercuric hydroxide (CH_3HgOH); and, to a lesser extent, dimethylmercury and phenylmercury.[3] Most organomercurics are not readily soluble and do not react with weak acids or bases due to the low affinity of mercury for oxygen bonded to carbon. However, methylmercuric hydroxide (CH_3HgOH) is highly soluble due to the strong hydrogen bonding capability of the hydroxide group. The mercuric salts vary widely in solubility, $HgCl_2$, $Hg(NO_3)_2$, and $Hg(ClO_4)_2$ are very soluble in water, whereas HgS is insoluble ($K_{sp} \approx 10^{-54}$). Further information on the chemistry of mercury can be found in the excellent discussions by Mason et al.[4] and by Nriagu.[5]

3 DISTRIBUTION AND USES OF MERCURY

3.1 Sources of Mercury in the Environment

As a naturally occurring element, mercury cannot be created or destroyed; mercury is present throughout the environment in both environmental media and biota. Mercury is found at trace levels in many minerals, with continental rocks containing an average of 80 mg Hg per kilogram (i.e. ppb).[6] Soil mercury concentrations may vary dramatically depending on the local geology and industry; typical soils are reported to contain 0.01–0.5 ppm.[7] Mercury is mined as the bright red ore cinnabar (HgS) predominantly in Russia, Spain, Mexico, and Algeria. Mercury is normally present in plant tissues in the range 30–700 ppb.[8] Mercury concentrations in waters vary, typical levels are reported as ranging from 0.0001 to 2.8 $\mu g\,Hg\,L^{-1}$ in fresh water, and from 0.01 to 0.22 $\mu g\,Hg\,L^{-1}$ in seawater.[7] The mercury content in air varies dramatically depending on the source, and is influenced heavily by volcanic and anthropogenic activities. Mercury in clean air is reported at $<0.01\,ng\,m^{-3}$, whereas contaminated air values for mercury range from 0.009–2.8 $ng\,m^{-3}$ in Europe, 0.07–38 $ng\,m^{-3}$ in North America, 1.6 $ng\,m^{-3}$ in Japan, to 18–250 $ng\,m^{-3}$ in Hawaii.[7]

Mercury is emitted into the environment by both natural and anthropogenic (human) processes. Input into the atmosphere occurs by degassing of the earth's crust, emissions from volcanoes, soil erosion, as well as from anthropogenic sources. Most mercury in the atmosphere is elemental mercury vapor. Anthropogenic activities that have contributed to emissions include burning

mercury-containing fuels and materials, and industrial processes. Fossil-fuel coal and lignite contain mercury, often at levels ≥ 100 ppb.[6] The largest contributions to mercury emission from human activities include coal-burning electrical utilities, municipal waste combusters, commercial and industrial boilers, medical waste incinerators, and chlor-alkali plants.[3]

3.2 Technical Uses

Historically, mercury has been used extensively (and still is to a lesser degree) in the extraction of precious metals (for example, gold and silver) as amalgams. The major use of mercury is in electrolytic cells (as the cathode) for the production of NaOH and Cl_2. Metallic mercury is used as a liquid contact material for electrical switches, in vacuum technology in diffusion pumps, thermometers, barometers, tachometers and thermostats, and in mercury-vapor lamps. Mercury is widely used in batteries. The standard calomel (Hg_2Cl_2) electrode, is used as the reference electrode for measurements of potentials in analytical electrochemistry. Mercuric oxide (HgO) has been used in antifouling paint for ships.

Mercury has been used in medicines, cosmetics, and in dentistry as silver amalgams for tooth restorations. Mercury chloride has been used in eye drops for newborns, for syphilis prophylaxis. Although banned in many parts of the world, mercury iodide (3%) or mercury amidochloride (10%) are used as skin-lightening creams and soaps by dark-skinned people.[9]

Organic mercury compounds have been used as pesticides, particularly fungicides. Mercury compounds used in this capacity include aryl mercurics such as phenyl mercuric dimethyldithiocarbamate, which was used as a slimicide and mold-retardant in the paper/pulp industry, and alkyl mercurics such as ethylmercuric chloride (C_2H_5HgCl) which is used as a seed fungicide. Organic mercury compounds are also used for their germicidal properties, for example phenyl mercuric acetate.

4 SAMPLE PREPARATION

4.1 Collection and Storage

Collection and storage are a critical part of any analysis for metals in environmental samples. Questions about trace-metal preservation and storage have resurfaced periodically over the years. These concerns stem from the health risk associated with certain metals, as the requirements for detection limits continue to lower. Because the mercury analytical technique is sensitive, great care in sampling protocols should be used. All sampling, storage and manipulation devices should be mercury free. Because of the risk of mercury in some laboratory environments, all laboratory equipment and sample collection tools should be stored in a clean mercury-free environment. Typical glassware/plasticware cleaning protocols include routine laboratory washing, rinsing with clean (mercury free) water, an acidic rinse and further rinsing with laboratory-grade clean (mercury free) water. The acidic rinses may be $1+1$ nitric acid, $1+1$ hydrochloric acid or aqua regia (three parts concentrated hydrochloric acid and one part concentrated nitric acid). Rinse times reported are for 12–24 h at room temperature, whereas some reports recommend rinsing at 70 °C for 24 h.

The type of analysis and matrix will dictate the sample collection, storage, and preservation protocols. For determination of mercury in waters the specific matrix may be: dissolved, suspended, total, or acid-extractable mercury, and this will dictate the type of collection protocol. Dissolved mercury analysis requires prefiltering samples prior to preserving. Filtration is typically through a 0.45-μm membrane filter. Preservation of other aqueous samples is typically with nitric acid (HNO_3) to pH < 2.0. The quality of nitric acid or other preservation chemicals should match the quality and precision of the analysis.

Unpreserved or acid-preserved mercury water samples may be collected in quartz, Teflon®, linear polyethylene, or borosilicate glass to prevent loss of mercury through disproportionation and volatilization. Polypropylene containers were found to be unsatisfactory unless the preservation included concentrated hydrochloric acid, reportedly to form the soluble $HgCl_4^{2-}$ complex.[10] Mercury concentrations may increase in samples stored in plastic bottles in mercury-contaminated laboratories; therefore, borosilicate or quartz is recommended for precise work. Glassware used in analyses where mercury is used as a reagent should be avoided (for example total Kjeldahl nitrogen (TKN), chloride or chemical oxygen demand (COD) procedures). Dedicated glassware for mercury-only analysis is ideal.

After acidification, it is recommended that samples be stored at 4 °C to minimize evaporation. Under these conditions, mercury is reported to be stable for only 5 weeks.[11] For longer-term storage of mercury, other procedures have been proposed, such as 5.0% HNO_3 and 0.05% $K_2Cr_2O_7$ – for example, 2 mL L^{-1} of 20% (w/v) $K_2Cr_2O_7$ in $1+1$ HNO_3 has been recommended.[12] This preservation procedure for mercury has been reported to be stable for up to 6 months in glass or 30 days in polyethylene containers.[10]

Although soil, sediments, and plant tissue samples may be analyzed without drying, most work is reported on a dry-weight basis. Moisture may be driven off in a drying oven at 60 °C. No mercury losses have been observed

by using this drying step.[3] The dry sample may be pulverized and thoroughly mixed before the aliquot is weighed. Samples should be stored in a dry, mercury-free environment until analysis.

Clinical sample collection and preservation include urine collected in glass or plasticware and preserved with glacial acetic acid or 1.5% nitric acid.[9] Blood samples are collected as blood–EDTA (ethylenediaminetetraacetic acid). Recommended storage is at 4 °C until analysis; samples should be analyzed as soon as possible. For tissue samples immediate freezing is recommended.[13]

4.2 Sample Pretreatment

Several authors recommend preparing mercury standard working solutions with about 2 μg L^{-1} potassium dichromate ($K_2Cr_2O_7$) for enhanced stability.[14,15] However, others have noted at high concentrations, 0.34 mM, that a 5% loss of sensitivity was seen after 24 h.[16] This pretreatment has also been recommended for sample preservation as discussed above.

4.3 Preparation of Environmental Samples

Most matrices require digestion of some type to free mercury from the inorganic and organic forms contained in the sample. Preparation/digestion methods for mercury analysis is still an active area of research.[17,18] However, two sample types which may be analyzed directly include clinical aqueous samples, such as urine, and environmental aqueous samples where the DQO (data quality objective) is for dissolved mercury only. All other matrices require decomposition, typically by wet oxidation mineralization (section 5.6 discusses other digestions). The organic and inorganic matrix must be decomposed (digested) and all mercury present must be converted (oxidized) to mercury(II) prior to the cold vapor process. The oxidized mercury is then reduced to elemental metallic mercury vapor by one of the cold vapor techniques (section 5.1).

The digestion methods (decomposition) may be generalized in that each approach uses a strong acid or combination of acids, such as nitric acid, hydrochloric acid, perchloric acid and/or sulfuric acid, generally in combination with an oxidant such as hydrogen peroxide, potassium permanganate, potassium dichromate, potassium persulfate, or vanadium oxide. The function of the acid(s) is to decompose the inorganic and organic matter of the biological matrix. A host of processes/mechanisms are needed to represent the whole decomposition of solids and/or organic matter; details of these processes are not present here, but an excellent review is available.[17] Briefly, most wet oxidation processes that involve organic matter are oxidative-hydrolytic processes. The samples are then typically treated with an oxidant. The purpose of the oxidant is to oxidize any organically bound mercury together with any unoxidized organic matter. In this way mercury is ensured to be in the soluble (nonvolatile) free form of Hg^{II}. The use of the oxidant potassium permanganate is described in Equation (1):

$$MnO_4^- + (\text{inorganic or organic}) - Hg \longrightarrow MnO_2 + Hg^{2+} + CO_2\uparrow + \text{inorganic salts} \quad (1)$$

Potassium chromate may be used in a similar fashion – samples may be preserved with an oxidant such as chromate to ensure that mercury remains as Hg^{2+}. Equation (2) illustrates how chromium(IV) prevents the loss of mercury through volatilization, by preventing the formation of Hg^0.

$$2CrO_4^{2-} + 16H^+ + 3Hg \longrightarrow 2Cr^{3+} + 3Hg^{2+} + 8H_2O \quad (2)$$

Potassium permanganate oxidizes many of these compounds, but some studies have indicated that a number of organic mercurials, including phenyl mercuric acetate and methyl mercuric chloride, are only partially oxidized by this reagent.[3] However, other studies have reported good recoveries of phenyl mercuric acetate using potassium permanganate.[14] Potassium persulfate has been reported to give good recoveries when used as the oxidant with these compounds.[3]

The digestions are routinely done at modest temperatures below 95 °C, due to the possible loss of mercury at elevated temperatures; for example, the bp of dimethylmercury is 96 °C. The exception to this is if closed-vessel digestions are used, such as microwave closed-vessel techniques or other sealed vessels such as Teflon®- or quartz-lined bombs, where losses of mercury are minimized.

Excess oxidant (e.g. hydrogen peroxide, potassium permanganate, potassium dichromate, potassium persulfate, or vanadium oxide) must be removed prior to the cold vapor chemistry. Excess oxidant will interfere (consume) the reducing reagent(s) in the cold vapor chemistry process, potentially leaving insufficient reagent for the mercury chemistry. The addition of reagents such as oxalic acid,[14] or hydroxylamine hydrochloride[19] reduces excess oxidant such as permanganate without reducing the mercury. Oxalic acid is added to reach the final end-point, which is a colorless solution (i.e. Mn^{2+} is colorless, MnO_4^- is purple, and MnO_2 is a brown precipitate;) Equation (3):

$$MnO_4^- + H_2C_2O_4 + 2H^+ \longrightarrow Mn^{2+} + 2CO_2\uparrow + 2H_2O \quad (3)$$

Oxalic acid does not react with the mercury, leaving it as nonvolatile mercury(II). This mild reduction should be performed immediately prior to the cold vapor process.

A typical digestion procedure might be described as follows: take 1 g of biological material, add 3 mL of concentrated nitric acid to a 10 mL digestion test tube, heat to 95 °C for 12 h, cool and treat dropwise with a saturated solution of potassium permanganate until the solutions remains purple (MnO_4^-) or a brown precipitate persists (MnO_2), heat to 95 °C for 10 min. Add oxalic acid to remove excess oxidant. Dilute to final volume and analyze by CVAAS (cold vapor atomic absorption spectrometry).

4.3.1 Clinical

Most techniques for the determination of mercury in solid matrices require a multistep approach. First, the conversion of all bound mercury in the sample to mercury(II) by a wet oxidation procedure (mineralization) and, second, the reduction of mercury(II) to mercury(0) vapor for analysis (discussed in section 5.1). If mineralization is required, the volatile nature of mercury should be kept in mind. There are numerous approaches to the digestion of clinical samples, as discussed above. Research on the determination of mercury in clinical and biological matrices has been extremely active over the last decade.

Most recently, the analysis of liquid clinical samples such as urine and blood have been analyzed directly, without pretreatment.[20] Blood samples analyzed directly often require the addition of an antifoaming agent (e.g. octanol) to the cold vapor reagents.[20] Numerous publications discuss the determination of mercury in biological matrices using several reagent combinations and equipment. These include microwave digestions[21–24] and various combinations of acidic wet decomposition.[14,18,19,23] Solid biological matrices are digested with acid, often with an oxidant.[13]

Hair samples are often pretreated with an acetone washing prior to digestion. The acetone removes dust and oils from the hair matrix, but otherwise the samples may be treated like other biological solid matrices.

4.3.2 Agricultural

Methods applicable to biological tissues are often validated with agricultural plant matrices.[14,22,25] Agricultural materials have been digested by a host of techniques, such as nitric–sulfuric acids with vanadium oxide.[15,26–28] Potassium permanganate is a favored oxidant for biological and agricultural matrices (including soils).[13,14,29] Closed-vessel digestions are gaining popularity for digesting agricultural matrices (plant material, soils and biological material) as microwave digestion ovens become more common in analytical laboratories.[29]

4.2.3 Waters

Depending on the DQO, the water sample type may be dissolved, suspended, total, or total recoverable. For dissolved mercury the samples are filtered prior to preservation, with a 0.45 μm filter. Suspended mercury is the sample left on the filter. Total mercury is the complete digestion of the entire original sample, and total recoverable is a caveat that some digestion techniques have yet to demonstrate recoveries from all forms of mercury. Digestion of water matrices may proceed as outlined above; increased sensitivity may be achieved by using larger samples.

5 ANALYTICAL METHODOLOGY

5.1 Cold Vapor Technique

Mercury is the only element that exists in metallic form at ambient conditions and at the same time exhibits a considerable vapor pressure. These unique properties enable unique methods of detection to be exploited. In addition, the traditional techniques, such as flame AAS, AFS, or ICPAES, exhibit poor mercury sensitivity. As mercury has a high vapor pressure (0.16 Pa at 20 °C), mercury may be determined by AAS without the use of an atomizer. Mercury must be simply reduced to metallic mercury from its compounds and transferred as the vapor phase. This is accomplished by a chemical reduction reaction used to generate the gaseous mercury species.

There are two primary advantages of the cold vapor process. First, the mercury analyte is removed from the sample matrix, which reduces the potential for matrix interferences. Second, the detection limits are improved because all of the mercury sample is introduced into the atomizer (or nebulizer in the case of ICPAES) within a few seconds. Therefore, the density of mercury in the cell during data collection (absorption, fluorescence, or emission, depending on the detection technique) is greatly enhanced as compared to typical sample introduction.

The two reducing agents used exclusively for cold vapor analysis are tin(II) and sodium borohydride. Tin(II) chloride ($SnCl_2$) was used in most early applications of mercury cold vapor analysis; more recently sodium borohydride ($NaBH_4$; the correct nomenclature is sodium tetrahydridoborate) has gained some favor. Tin(II) chloride reacts with mercury as described by Equation (4):

$$Sn^{2+} + Hg^{2+} \longrightarrow Sn^{4+} + Hg^0 \qquad (4)$$

The tin chloride technique requires that the metallic mercury be transported by an inert gas stream (for example argon or nitrogen) bubbled (purged) through the solution to drive out the mercury to the absorption

cell. Later applications use tin sulfate (stannous sulfate) instead of tin(II) chloride.[29,30]

Sodium borohydride in an alkaline solution is becoming the preferred reagent; it requires no other reagents for the reduction. Sodium borohydride is a stronger reducing agent than tin(II) chloride. In addition, sodium borohydride produces dihydrogen as part of the reduction chemical reaction. The hydrogen can therefore transport the majority of the metallic mercury from the solution into the absorption cell. The sample digestate is acidic from the mineralization process (Equation 5):

$$BH_4^- + H^+ + 3H_2O \longrightarrow H_3BO_3 + 8H^\bullet + Hg^{2+} \longrightarrow Hg^0 + 4H_2 \quad (5)$$

Sodium borohydride, which is prepared in basic media (e.g. NaOH) for stabilization purposes, should be prepared daily. Because of the production of hydrogen, the borohydride technique is limited to open systems.

5.2 Instrumental Developments

The cold vapor method for mercury has been described for several instruments, including AAS (most favored), AFS, and ICPAES. The earliest report of using mercury vapor, to monitor mercury in air, was in 1939 by Woodson.[31] Later the use of Sn^{II} to produce mercury vapor was reported by Kimura and Miller,[32] and this approach was subsequently optimized by Poluektov et al.[33] One of the early descriptions of CVAAS for the analysis of mercury in environmental samples, soil and rock, was by Hatch and Ott in 1968.[34] Cold vapor generators of numerous special designs have subsequently been described in the literature.[35]

Overall, the CVAAS technique may be categorized as batch or flow systems. The AAS procedure is a physical method based on the absorption of radiation at 253.7 nm by mercury vapor. The mercury is reduced to the elemental state by the cold vapor process and aerated from solution. All of the mercury in the sample solution placed in the reaction vessel is chemically atomized and transported to the sample cell for measurement. The mercury vapor passes through a cell positioned in the light path of an atomic absorption spectrophotometer. Absorbance (peak height) is measured as a function of mercury concentration.

In the batch mode, specific volumes of sample and reductant are mixed at the start of the process, which culminates in the generation of a transient absorbance signal. A typical batch system for cold vapor generation is shown in Figure 1. The advantages of a batch system are that large volumes may be used, which increase sensitivity; sample volumes of 50 mL are routinely reported. The disadvantages include large reagent consumption, large dead volume, and the method is relatively slow and labor intensive.

Figure 1 Batch system for mercury cold vapor generation.

In the flow injection system reagents are continuously pumped, the sample is injected into the carrier flow, and the flow then ultimately goes through a reaction (mixing) coil and a gas–liquid separator, thereby generating a transient absorption signal. In a continuous flow system the reagent and sample are continuously pumped, and the system flow proceeds as described above for flow injection. As the sample and reagents are continuously pumped through the system, this technique generates a continuous, flame-like absorbance signal. A typical continuous flow system for cold vapor generation is shown schematically in Figure 2. The advantages of a flow injection system are that smaller sample volumes are used, with consequent lower reagent consumption. The continuous and flow injection techniques are easily automated. Dead volume is reduced, which results in greater absolute sensitivities. Overall, the batch and flow techniques have similar absolute sensitivities, although batch systems use larger sample volumes to achieve the same sensitivity. Both systems have unique attributes and their suitability will depend on the application.

Any atomic absorption unit having an open sample presentation area capable of mounting an absorption cell is suitable. Instrument operating parameters are set according to the manufacturer. Instruments designed

Figure 2 Flow system for mercury cold vapor generation.

specifically for the measurement of mercury using the cold vapor technique are commercially available and may be substituted for the atomic absorption spectrophotometer. Standard spectrophotometer cells 10 cm long and having quartz end windows may be used; alternatively, suitable cells may be constructed from plexiglass tubing.

Cold vapor for AFS works on the same principles as for AAS. The increase in sensitivity is a function of the selectivity of introducing mercury vapor into the instrument detection system, while eliminating most of the rest of the matrix constituents through the liquid waste. A CVAFS (cold vapor atomic fluorescence spectrometry) system consists of a vapor generator, mercury fluorescence detector, and measurement/computer system. The mercury vapor is removed in a gas–liquid separator by an inert gas (e.g. argon), the mercury is piped through a chimney past a light source and photomultiplier that are at right angles to each other. As the vapor absorbs the mercury light, it fluorescences at the same wavelength (typically 254.7 nm). The design allows for the efficient isolation of the required excitation and emission wavelength for sensitive quantitation of mercury. Numerous cold vapor techniques have proven satisfactory for this technique. Instrument operating parameters are set according to each particular manufacturer. Mercury sensitivities of 4–10 ng g^{-1} have been reported.[36]

Cold vapor may also be used in ICPAES applications, i.e. CVICPAES (cold vapor inductively coupled plasma atomic emission spectrometry). Mercury(II) is reduced by sodium borohydride in a continuous manifold. A standard pneumatic nebulizer effects the gas–liquid separation of mercury and concentrates the mercury into a small plug of gas, which is carried to the plasma. A cold vapor flow system for ICPAES is shown in Figure 3. This also provides longer residence time in the plasma, which further increases sensitivity.[14] The introduction of volatile mercury increases the sensitivity by over 1000-fold as compared to liquid sample introduction for ICPAES analysis. This increase is because the transport efficiency of the gaseous mercury to the plasma is higher. In addition, atomization and excitation of the gaseous mercury is very efficient because the process avoids the energy-consuming desolvation and vaporization phases associated with liquid samples. Matrix effects are also minimized as most of the other constituents in the samples are in the liquid fraction and are directed past the sample introduction system in the ICPAES and into the waste stream. Instrument operating parameters are set according to each particular manufacturer. Mercury is quantitated by ICPAES at 194.232 nm. The sensitivity is reported to be 0.2 μg L^{-1}. Gas–liquid separators for ICPAES are commonly used and are available from many manufacturers; they may be used with either tin(II) or sodium borohydride. These same gas–liquid separators are also used for hydride generation for ICPAES.

5.3 Amalgamation

As the need for lower and lower detection limits is required by the analytical community, further enhancement of the cold vapor technique has continued to evolve. Again, capitalizing on the unique properties of mercury affords yet another development in the enrichment of the cold vapor technique. Mercury readily forms amalgamations with precious metals. With this technique, mercury is reduced to Hg^0 vapor and transported by an inert gas (for example argon) in the typical manner used in the cold vapor technique. In this application, the mercury vapor is passed through an absorber,[37] for example a gold gauze, where it is retained (Figure 4). In this way, mercury may be collected from large sample volumes or over extended periods, or both, thereby permitting high preconcentration factors. The mercury is subsequently released by rapidly heating the absorber to about 600 °C and mercury is determined in the typical manner. Detection limits of 3 ng L^{-1} have been reported.[9]

Figure 3 Continuous flow manifold for mercury cold vapor generation for ICPAES.

Figure 4 Batch mercury cold vapor generator with drying agent and gold amalgamation preconcentration.

Table 1 Mercury cold vapor detection limits

Cold vapor technique	Mercury sensitivities ($\mu g\,L^{-1}$)	Refs.
CVAAS	0.2	3, 9, 38
CVAFS	0.004–0.010	3, 36, 38
CVICPAES	0.2	14
Amalgamation CVAAS	0.003	9, 22, 38

5.4 Detection Limits

Detection limits depend in some measure on the matrix to be analyzed. The matrix may also dictate the type of analytical approach, together with the sensitivity requirements (Table 1).

5.5 Interferences

The most frequent source of error in the determination of mercury is typically the digestion which either does not break down the organomercury compounds or does not convert all of the mercury to the proper oxidation states. The other major source of error is mercury contamination from the laboratory environment. Typically, spectral and chemical interferences are of minor consequence in comparison. One of the primary advantages of the cold vapor process is that the analyte (mercury) is removed from the sample matrix, which reduces the potential for interferences. The matrix constituents are normally left in the reaction vessel. Therefore, due to the small number of constituents in the gas phase in the atomizer (nebulizer) spectral interferences are virtually excluded. Possible interference from water vapor was thought to interfere with the absorption at 253 nm in AAS analyses; this was later determined not to be a spectral interference.[38] The water interference was due to droplets of solution, which were carried by the gas stream and subsequent condensation of the vapor in the absorption cell, reducing signal intensity. The water interference can be eliminated by either using a suitable drying agent or by warming the AAS absorption cell.

Fortunately, chemical interferences are nearly excluded for the two most common techniques used in the mercury cold vapor generation, namely Sn^{II} and sodium borohydride. Metals that can be reduced form fine particulate material, which can retain mercury. Tin(II) chloride is not a strong reductant; therefore, it does not reduce many other metals which may be present in the matrix. Selenium and iodide are the only elements that have appreciable effects on the Sn^{II} reaction.[38] Sodium borohydride is a strong reductant; copper, and nickel, may form particulates which can retain mercury. The concentrations in most typical environmental matrices, which are required of these elements to interfere, seldom exceed the range of interference-free determination. Hazardous waste or other matrices with unique or high concentrations of these trace elements should be evaluated individually for potential interferences.

The hydride-forming elements may cause interference in the gas phase; Sn^{II} is a weak reductant and therefore represents a minor source of error. Sodium borohydride easily forms hydrides (with As, Se, etc.) and therefore can represent a large source of error, depending on the concentration of these hydride-forming elements.

Sodium borohydride also may reduce metals such as gold, silver, palladium, and platinum; mercury can form amalgams with these metals, thereby causing a suppression of the mercury signal.[38] It has been shown that increasing acid concentration in the sample solution reduces interference from these metals.[9] It has also been shown that the flow injection AAS system is less susceptible to interferences of this type. These types of interference are caused by the reduced form of the interferent, because the reduction takes some finite time; if flow conditions are optimized the mercury vapor reaches the absorption cell before significant amounts of interferent are precipitated and retain mercury (a kind of kinetic discrimination[38]).[9]

Nitric acid digestions used with sodium borohydride as the reducing agent in a flow injection AAS can cause poor reproducibility for mercury determination. It has been reported that the interference was due to inhibition of the mercury reduction by the volatile nitrogen oxides which were scavenging the reducing agent.[39] This interference can be overcome by purging the sample with an inert gas (e.g. argon).

Seawaters, brines and industrial effluents high in chlorides require additional permanganate. During the oxidation step, chlorides are converted to free chlorine, which will also absorb radiation at 253 nm.[3] This causes an enhancement of the signal. Care must be taken to ensure that free chlorine is absent before the mercury is reduced and swept into the cell. This may be accomplished by using an excess of hydroxylamine sulfate reagent. Alternatively, a sulfuric acid/dichromate digestion has been used successfully on high-chloride-content matrices.[38] Other reports ascribe the interference of chlorine on the mercury cold vapor technique to the re-oxidation of elemental mercury by chlorine inside the reduction–aeration system, causing suppression of mercury recovery.[40] Nonchemical removal of the chlorine interference has been accomplished by the use of an additional heating step after digestions, which allows evaporation of chlorine yet retains mercury in the sample solution.

Report on CVICPAES analyses indicate no chemical interference for sodium, calcium, potassium, magnesium, chromium, manganese, iron, cobalt, nickel, copper, aluminum or zinc at 0.4%.[14] Copper at or above 1000 $\mu g\,g^{-1}$

did interfere with the mercury emission signal,[14] copper was observed to be plating out on the tubing.

Possible interference from sulfide is eliminated by the addition of potassium permanganate. Concentrations as high as $20\,mg\,L^{-1}$ of sulfide as sodium sulfide do not interfere with the recovery of added inorganic mercury from distilled water.[3]

5.6 Speciation

Speciation of mercury is meaningful because of the toxicity of certain mercury compounds, and the importance of understanding the movement, bioaccumulation, and transformations of mercury. Methylation of mercury is the critical reaction in the entry of mercury into the food chain. Biotransformation of inorganic mercury species to methylated organic mercury species occurs in the sediment and water column. However, not all inorganic mercury is converted to methylmercury; reactions such as demethylation and volatilization also occur.[3] The rates of these reactions are not well understood. All forms of mercury accumulate to some degree in organisms, but methylmercury accumulates to a much greater extent. In addition, elimination of methylmercury by organisms (e.g. fish-eating birds, fish, and humans) is slow compared to inorganic forms of mercury. The toxicological risks of methyl mercury compounds are therefore more significant.

Speciation of mercury is a relevant analytical goal because, as yet, no single method permits unequivocal identification of all mercury species. More often, broad classes of mercury such as ''inorganic mercury'' and ''organic mercury'' are commonly reported. One of the early works on mercury speciation was based on the preparation of a biological sample using alkaline digestion,[41,42] often referred to as the Magos method. The method depends in part on the reaction rate kinetics for conversion of methylmercury by the reductant to be slow compared to the analytical process. The sample preparation is based on alkaline digestion with NaOH and cysteine. Briefly, about 1 g of sample is solubilized in 10 mL of 1:1:1 1% NaCl, 45% NaOH and 1% cysteine at 80 °C.[43] The cysteine is thought to complex with mercury and minimizes mercury volatility.[44] The high-pH sample is then reduced with the addition of tin(II) to form metallic mercury vapor as described in Equation (4); the sample is then analyzed in typical fashion by AAS. The mercury determined in this manner is termed inorganic mercury. Total mercury is analyzed by the same procedure, but a Sn–Cd reductant is used which reduces inorganic and organic mercury to metallic mercury vapor. Organic mercury is estimated as the difference between total and inorganic mercury. Current reports indicate that this technique overestimates the concentration of inorganic mercury in the presence of methylmercury.[43] Degradation of methylmercury during the formation of the analytical signal is thought to account for the overestimate.[43] Similar approaches, such as staging digestions, have been used with some success.

Most recent reports depend on hyphenated methods for speciation,[45,46] such as liquid chromatography (LC)/ICPMS, (inductively coupled plasma mass spectrometry)[47] electrothermal (ET)/ICPMS,[48] and gas chromatography (GC)/CVAFS.[49] Other speciation methods include physical/mechanical separation (separation based on molecular size), and potentiometric methods (separation based on differences in electrical potential).

6 ENVIRONMENTAL REGULATIONS

Concentrations of mercury in air and water are typically low, and pose little health risk. However, once mercury enters water, either directly or through air deposition, it can bioaccumulate in fish and animal tissue as methylmercury. Human exposure to mercury occurs primarily through eating contaminated fish. Exposure to high levels of mercury has been associated with serious neurological and developmental effects in humans.[3]

Table 2 lists some examples of environmental mercury standards, including some drinking water limits from various agencies and countries. Because of the diverse mechanisms by which mercury may be introduced into the environment, mercury regulations often span several agencies. The USEPA regulates mercury in pesticides and mercury releases into the environment (air, water, and land disposal), the FDA regulates mercury in

Table 2 Environmental regulatory standards for mercury[3,7]

Environmental matrix	Mercury limit ($\mu g\,L^{-1}$) or ($\mu g\,Kg^{-1}$)	Agency or country
Fish	1000	FDA (USA)
Ingesting aquatic organisms and water	0.144	USEPA
Air	0.01 mg m^3 eight hour limit	USOSHA
Drinking water	1.0	World Health Organization
Drinking water	2.0	USA
Drinking water	0.5	Japan
Drinking water	1.0	Chinese (proposed)
Drinking water	1.0	UK

FDA, Food and Drug Administration; USEPA, United States Environmental Protection Agency; USOSHA, United States Occupational Safety and Health Administration.

Table 3 Summary of USEPA methods for mercury analysis

Method number	Matrix	Digestion, instrument, sensitivity, comments
0060	stack emissions	Hg collection procedure, analysis by 7470 (CVAAS)
200.15	aqueous	ICPAES ultrasonic nebulizer, 3 μg L^{-1}
245.1	aqueous	CVAAS, batch system, 0.2 μg L^{-1}
245.2	aqueous	CVAAS, flow system, 0.2 μg L^{-1}
245.5	sediments, solids	CVAAS, batch system, 0.2 μg g^{-1}, aqua regia digestion
1620	all environmental	consolidation of methods 245.1, 245.2, and 245.5
1631	aqueous	CVAFS, oxidation, purge and trap, 0.5 ng L^{-1}
1669	all environmental	Hg sampling ambient water protocol
3051	soils, sludges, etc.	digestion procedure only, microwave–nitric acid
3052	organic material	digestion procedure only, microwave–nitric acid
6010B	predigested	ICPAES method only, detection limit ca. 17 μg L^{-1}
7470A	liquid waste, etc.	CVAAS, batch system, nitric/sulfuric acids, $KMnO_4$
7417A	solid waste, etc.	CVAAS, aqua regia, $KMnO_4$
7472	solids, aqueous	ASV, mercury(II) only, 0.1 μg L^{-1}

food, cosmetics and dental products, and the USOSHA regulates mercury in air exposure in the workplace.

The USEPA program for water, Contract Laboratory Program (CLP), and the Resource Conservation and Recovery Act (RCRA) accept results from several different digestions/instruments. A summary of USEPA methods for the determination of mercury is given in Table 3.

7 QUALITY CONTROL AND TROUBLESHOOTING

7.1 Data Quality Objectives

The DQOs are typically project defined. Spikes and check standards will typically have >95% recovery. Concentrations close to the detection limit will have inherently more variability. Typically, recoveries of SRMs (standard reference materials) are reported at >85% for total mercury. Speciation of mercury is currently not reported to be nearly as accurate, with some species of mercury recovered at <85%. Speciation of mercury is still an active research area.

7.2 Instrument Performance

A good, general preventive maintenance program will keep equipment in top performance longer and therefore is highly recommended. A review of troubleshooting is beyond the scope of this article and has been covered elsewhere.[10,13,28] Briefly, in the case of erroneously low results or no signal, cold vapor reagents should be checked to ensure they are mixing and have not deteriorated; other items to check are gas lines, contamination of blank, and matrix interferences. In the case of erroneously high results, check that blank correction was performed properly and that standards have not deteriorated, also check for memory effects and matrix interferences.

7.3 Standard Reference Materials

A minimum number of quality control (QC) samples should be analyzed as part of the QC program defined by the DQOs, as follows. Laboratory blanks prepared with the samples are a matrix blank, used to cancel interference or contamination from reagents or analytical manipulations and should be included in the analytical batch. Laboratory spikes should be analyzed for. An example would be to prepare by spiking a sample with 50 ng mL^{-1} of 1 mg L^{-1} mercury solution and calculating the percentage recovery; other concentrations may be more appropriate depending on the specific application. If the recovery falls within 85–115%, the analysis has passed QC; the recovery window is defined by the project DQOs. SRM should be included in the analytical batch. Depending on the matrix, the best possible similar SRM should be included. Examples are: NIST (National Institute of Standards and Technology), oyster tissue, NIST pine needles, NIST bovine liver, and NIST citrus leaves (for biological matrices); NIST Buffalo River sediment, National Research Council of Canada (NRC) estuarine sediment, NRC harbour sediment, BCR (European Commission, Belgium) river sediment, BCR light sandy soil, BCR sewage sludge amended soil, BCR sewage sludge of domestic origin (for soils, sludge, and sediment matrices). For aqueous environment samples NIST, NRC, BCR, or other vendor's trace-metal SRMs should be included. The SRM should have mercury levels within the concentration ranges that are expected in the samples to be analyzed. In-house SRM may be substituted if a sufficient confidence level can be demonstrated with the mercury concentration. The frequency of the QC samples depends on the project DQOs; 10% of each QC type is often used as a default frequency; SRMs for the speciation of mercury are currently inadequate/unavailable.

Table 4 Instrument sensitivities for mercury non-cold-vapor techniques

Technique	Mercury sensitivities ($\mu g\,L^{-1}$)	Refs.
Anodic stripping voltametry	0.5–1.0	9, 50
Flame AAS	2200	50, 51
ETAAS	0.5	50, 51
ICPAES	10–50	50, 51
NAA	3	50, 51
ICPMS	0.01–0.001	51, 52
AFS	0.2	50, 51

ETAAS, electrothermal atomic absorption spectrometry; NAA, neutron activation analysis.

8 METHOD COMPARISON

8.1 Instrumental Technique Comparison

Detection limits depend in some measure on the matrix to be analyzed. In addition, the matrix dictates the type of analytical technique approach, in addition to sensitivity requirements. Detection limits using the cold-vapor process for detection of mercury are given in Table 1. Instrument detection limits for non-cold-vapor techniques are given in Table 4.

8.2 Other Techniques

There are numerous approaches to mercury analysis and some techniques require fairly specialized equipment. Mercury in environmental matrices has been routinely determined by several techniques,[13] including CVAAS, ETAAS,[53] AFS,[54,55] CVICPAES,[14] GC/MS,[56] ICPMS,[52,57–59] and NAA.[60,61] Examples of some selected mercury methods specifically for water and environmental aqueous solutions include LC/ICP/MS (liquid chromatography/inductively coupled plasma/mass spectrometry),[62,63] X-ray fluorescence (XRF),[64] and spectrophotometric techniques.

This report describes innovative methods for sample pretreatment in organic environmental analysis that involve the use of microwave-assisted techniques. The methods described include: microwave-assisted extraction (MAE), focused microwave-assisted Soxhlet extraction (FMASE), microwave-assisted headspace analysis, microwave-assisted derivatization (MAD), microwave-assisted saponification (MAS) and microwave-assisted decomposition. A brief history of the development of each technique is provided. Reference is made to literature published up to the beginning of 1999.

1 INTRODUCTION

Modern analytical instruments can offer extremely low detection limits with high precision, resolution, reproducibility and speed of operation. But most of these methods require quite extensive sample pretreatment due to the great complexity of analytes and matrixes in environmental samples. This is usually the most time-consuming step in the whole analytical process. Therefore, the development of novel methods and techniques for sample pretreatment has attracted a great deal of attention from researchers. Since the mid-1980s a number of innovative pretreatment techniques have been introduced. These include: supercritical fluid extraction (SFE),[1] solid-phase extraction (SPE),[2] solid-phase microextraction (SPME),[3] the supported liquid membrane (SLM) technique for extraction,[4] accelerated solvent extraction (ASE)[5] and high-performance capillary electrophoresis (HPCE).[6] This report will outline other innovative methods for sample pretreatment in organic environmental analysis that involve the use of microwave-assisted techniques.

Interestingly enough, the first recorded uses of microwave ovens in chemical laboratories involved sample pretreatment in preparation for analysis. In 1974, Hesek and Wilson reported that a commercial microwave oven was employed to dry inorganic samples in process control,[7] then subsequently Abu-Samra et al. reported the use of microwave energy for the wet ashing of some biological samples prior to determination of metals content.[8] But the major breakthrough came with the development of microwave-assisted acidic pressure digestions[9,10] and microwave-assisted chemical synthesis[11,12] and the subsequent availability of cheap, microwave-transparent vessels able to withstand the rigorous conditions. Since then, this approach has been progressively established as a standard method for preparation of samples for elemental analysis.[13–15] Recently, microwave energy has been further employed to develop a four-stage sequential extraction method for metal fractionation in soil and sewage sludge samples.[16,17]

In the mid-1980s, Ganzler et al. pioneered the use of microwave energy for organic extractions in sample pretreatment.[18] They used microwave radiation from a conventional household microwave oven to enhance the extraction of various types of organic compounds from soil, seeds, foods and feeds. This MAE method gave higher recoveries and proved environmentally friendly in yielding considerable savings in time, energy and solvent compared with the conventional methods. Moreover, MAE had the advantage of being admirably suited for the isolation of thermally labile substances due to the dramatic savings in extraction time. The advantages of MAE have led to its widespread acceptance by practicing analysts in this field.

In addition, a series of new microwave-assisted techniques, such as MAS,[19] MAD[20] and microwave-assisted decomposition[21] have also been successfully developed in the last few years. These techniques can be separately employed for sample pretreatment in organic analysis or used in combination with MAE.

R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

Details of the various microwave systems available and the theoretical basis of microwave heating are given elsewhere in this volume. Several useful reviews have appeared which put the various developments into perspective and demonstrate the wide applicability of microwave-assisted processes.[13,14,22–27]

2 MICROWAVE-ASSISTED EXTRACTION

Of all the microwave-assisted techniques for sample pretreatment for organic environmental analysis, MAE is the longest-established, best-studied and most widely-used. In performing MAE, a number of important parameters must be controlled, including sample size, solvent (extractant) type and volume, microwave irradiation time, magnetron power output and the temperature of the extraction system. The pressure in the sample vessel is also important when a closed-vessel system is used for MAE. All the parameters can be optimized by chemometrics and factorial design. Generally, the duration of an MAE cycle is less than 30 min, of which microwave irradiation time is about 10 min, and the quantity of solvent needed is less than 50% of that required for traditional Soxhlet extraction. The two principal microwave systems employed for MAE are the closed-vessel MAE system and the open focused microwave-assisted extraction (FMAE) system. For the FMAE both an open-vessel and a focused microwave unit are employed. There are some significant differences in experimental parameters and application areas between these two techniques.

MAE has been used in isolating a variety of analytes from a range of sample types. The increasing applications of this method are described in several review articles.[13,15,23,28–34] The original work by Ganzler et al. involved isolating various types of organic compounds and biologically active compounds from seeds, foods, feeds and rat feces.[18,35–37] This type of application of the process has been continued and expanded. In two patents held by Pare et al., the extraction of essential oils and other oils from biological materials such as plant and fish tissue,[38] and extraction of natural products from mint, garlic, etc.,[39] have been described. Prior to the issue of these patents, Craveiro et al.[40] also developed a method for the extraction of essential oils from fresh plant materials, which made use of MAE. In addition, the extraction of the essential oil components from rosemary leaves, including a study of the kinetics of the MAE process, has been reported by Chen and Spiro.[41] The extraction of antibodies from the surface of red blood cells was investigated by Torloni et al.[42] Banerjee et al.[43] have reported a microwave-based DNA extraction from paraffin-embedded tissue for polymerase chain reaction (PCR) amplification. Young[44] has used the technique for isolating the fungal metabolite ergosterol and total fatty acids. Leray et al.[45] reported an MAE method for lipid analysis in biological samples with an open-vessel microwave system. Akhiar and Croteau[46] described the MAE of salinomycin from finished layers ration. Carro et al.[47] studied the extraction of monoterphols from must samples, while Wang et al.[48] reported isolating Veltol® and Veltol-Plus® using MAE.

In addition to its applications in bioanalysis, food analysis and natural products extraction, MAE has also been used in isolating additives from polymers[34,49–51] and in the extraction of oligomers from poly(ethylene terephthalate) (PET).[52]

Probably the greatest number of reported applications of MAE involves sample preparation for organic environmental analysis. Examples include extracting polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), organophosphorus pesticides (OPPs), phenolic compounds, chlorinated benzenes, petroleum hydrocarbons, triazines, imidazolinone herbicides, sulfonylurea herbicides, methylmercury and other organometallic compounds, from soils, sediments, sewage, air particles, plants, and tissue from marine mammals.[18,20,21,53–91] Polychlorinated dibenzo-*p*-dioxin (PCDD) and polychlorinated dibenzofuran (PCDF) were also extracted from solid samples such as fly ash, soil, wet sediment and sewage sludge.[58] The work of Lopez-Avila et al.[32,55,56,82,83] in evaluating the relative merits of MAE and the standard methods used by the United States Environmental Protection Agency (USEPA) for the extraction of the principal organic pollutants is worthy of note. Their research results demonstrate[55,56] that most of these compounds can be recovered in good yields from the soil/sediment samples that they studied using MAE. For example, they report recoveries of 80–120% for 79 of the 95 compounds listed in USEPA Method 8250,[92] 38 of the 45 OCPs listed in Method 8081,[93] and 34 of the 47 OPPs listed in Method 8141A.[94] For 15 compounds in a reference soil, the recoveries of 14 compounds by MAE were equal to or better than recoveries obtained by Soxhlet extraction (naphthalene being the exception). For selected OCPs, recoveries from spiked soil samples were at least 7% higher for MAE than for either Soxhlet or sonication extraction. Moreover, MAE also compared favourably with SFE.[83] In summary, it would appear that MAE can minimize pollution in the laboratory, improve target analyte recoveries and reduce sample preparation costs.

As well as being used for isolating organic analytes from diverse solid matrixes, MAE can also be applied to the

preparation of water samples. For example, microwave protocols for the extraction of PCBs and chlorinated benzenes from water samples have been developed by Onuska and Terry.[80,81] The use of aqueous extractants is especially suited to microwave-assisted techniques, and several new methods have been reported.[62–66] The MAE method has been used in combination with other extraction techniques such as SPE[85,86] and SPME.[48]

The methods which use MAE in combination with MAD, saponification, saponification–derivatization, decomposition or saponification–decomposition, will be discussed in the appropriate sections of this article.

A selection of cited applications of MAE for sample preparation in organic environmental analysis is given in Table 1. Although several nonpolar or weakly polar solvents are listed as extraction media, it is essential that some moisture or polar solvent be present in the system to enable the absorption of the microwave energy.

Table 1 MAE for sample preparation in organic environmental analysis

Sample	Analyte	Extractant (solvent)	Ref.
Soil	OPPs (bromophos, parathion)	Methanol	20
Sediment	OCPs	Isooctane–acetonitrile, 1 : 1	53
Sediment	Trialkyl and triaryl phosphates	Hexane/DCM	54
Soil, sediment	PAHs, base/neutral compounds, phenols, OCPs	Acetone–hexane, 1 : 1 (v/v)	55
Topsoil	187 compounds of interest to USEPA, 5 Aroclors (PCBs)	Acetone–hexane, 1 : 1 (v/v)	56
Soil	PAHs	Acetone, acetone/hexane	57
Solid samples (sediment/soil/fly ash, etc.)	PCDD, PCDF	Toluene	58
Marine sediment	OCPs	Acetone–hexane, 1 : 1 (v/v)	59
Marine sediment	PAHs	Acetone–hexane, 1 : 1 (v/v)	60
Ambient-air polyurethane foam	PAHs and their surrogates	Cyclohexane	61
Soil	Imidazolinone herbicides	0.1 M NH_4OAc/NH_4OH, pH 10.0	62
Plant tissue	Imidazolinone herbicides & their metabolites	H_2O	63
Soil	Atrazine and its degradates	0.35 M HCl	64
Soil	Atrazine	H_2O	65
Soil	Atrazine, simatrine, prometryne	H_2O	66
Soil, sediment, mussels	PCBs	Methanolic 1 M KOH solution	21
Marine mammals	Organochlorine compounds	Hexane	67
Soil	Phenol and methylphenol isomers	Acetone/hexane	68
Soil	Phenolic compounds	Hexane/acetic anhydride/pyridine In situ MAE/MAD	69
Sediment	Hydrocarbons, pesticides	Toluene–water, 10 : 1 (v/v)	70
Plants	PAHs	Hexane–acetone, 3 : 2 (v/v)	71
Soil	Phenolic compounds	Methanol–water, 4 : 1, with 2% TEA	72
Soil	Sulfonylurea herbicides	DCM–methanol, 9 : 1	73
Sediment	OCPs	THF	74
Sediment	PAHs	DCM	75
Soil, sewage	PAHs, PCBs	Hexane–acetone, 3 : 1	76
Air particles	PAHs	Acetone–hexane, 1 : 1 (v/v)	77
Soil, sewage	PCBs	Hexane–acetone, 3 : 1	78
Water, olives, sunflower, etc.	Edible oils, mineral oils, petroleum, gasoline, etc.	CCl_4	79
Water	PCBs	Isooctane (NaCl was added)	80
Water	Chlorinated benzenes	NaCl was added, helium used to purge the analytes into hexane	81
Sediment	Methylmercury	Toluene (6 M HCl was added)	88
Sediment	Methylmercury	2 M HNO_3	89
Mussels	Arsenic species	Methanol/water	90
Sediment	Organotin compounds	Methanolic 0.5 M ethanoic acid	20
Biomaterial	Organotin compounds	Acetic acid	91

DCM, dichloromethane.

3 FOCUSED MICROWAVE-ASSISTED SOXHLET EXTRACTION

One of the most recent applications of microwave energy for sample pretreatment in organic environmental analysis is FMASE, which has recently been described by Garcia-Ayuso et al.[95] The device itself consists of two main parts: the microwave irradiation zone, which includes a modified Prolabo Microdigest 301 (200 W maximum power) microwave source along with a modified Soxhlet extractor, and a distillation flask which is connected to a cooling unit. Two peristaltic pumps are used for solvent aspiration and siphoning in addition to the Soxhlet action. A special thermometer is used for monitoring the extraction temperature; three monitors control the microwave unit, pumps, and the thermometer. An electrical mantle is used as a heating source for the distillation flask.

The FMASE apparatus described above has been used to extract three different kinds of organic contaminants, namely alkanes, PAHs and herbicides, from clay soil. DCM was used as the extractant. For a 7-g sample, ultrapure water (1.0 mL or 1.5 mL) was added to the cartridge and the sample was allowed to soak for 10–15 min (water mainly acts to enhance the absorption of microwave energy). Then, the cartridge thimble was covered with a loose wad of glass wool and inserted into the extraction vessel, which was placed in the microwave irradiation zone. The extraction was performed as follows:

1. the extraction vessel was filled with 50 mL of fresh extractant delivered by pump 1;
2. the sample was subjected to microwave irradiation for 15 s at 50% of maximum power output;
3. the extraction vessel was drained by pump 2.

This extraction cycle was repeated a number of times depending on the target analytes. The duration of each cycle was 6 min, so a whole extraction program took 50–60 min.

The results of the study demonstrate that:

- FMASE provides efficiencies similar to those obtained by the conventional Soxhlet method with extraction times at least eight times shorter (50–60 min versus 8 h).
- FMASE can be used for almost all the applications of a conventional Soxhlet extraction under similar operating conditions.
- FMASE can be used for treating wet samples whereas the conventional Soxhlet method is usually suitable for dry samples only.

4 MICROWAVE-ASSISTED HEADSPACE ANALYSIS

The isolation and analysis of the volatile organic compounds (VOCs) in water samples may be carried out by transferring the volatile material in the headspace above the liquid surface to a gas chromatography (GC) device. Pare et al. have made use of microwave heating to improve the conventional headspace method.[96] The standard headspace sampler is still used to sample the vapor above the water and then to transfer the analytes into a GC device but the different method of heating gives very significant improvements in isolating efficiency.

The VOCs, namely benzene, methylbenzene, ethylbenzene, chlorobenzene, *o*-, *m*-, and *p*-xylenes, and 1,2-, 1,3-, and 1,4-dichlorobenzene, were isolated from both spiked and actual samples at parts per trillion (ppt) to parts per million (ppm) levels. Compared with the conventional headspace method, this new technique offers enhanced sensitivity as evidenced by a 35% increase in signal strength and a dramatic reduction in the time required for the establishment of equilibrium (from 30 min to 1 min).

5 MICROWAVE-ASSISTED DERIVATIZATION

Since the first studies by Smith et al.,[11,12] the use of microwave energy for the acceleration of organic reactions has increased enormously.[22,97] Recently, microwave-assisted esterification was used for the gas chromatography/mass spectrometry (GC/MS) determination of fatty acids in food oils.[98] The esterification of the fatty acids was carried out in methanolic 0.4 M KOH solution in a closed vessel with 30 s of microwave irradiation (600 W). Considerable savings of time and solvent were obtained with this method as compared with the conventional derivatization procedure.

Although derivatization reactions were among the first studied by the early researchers in this field,[99] the use of MAD for sample pretreatment in organic environmental analysis first appeared in a report by Lalere et al.[20] For the speciation analysis of organotin compounds in sediments by capillary GC with flame photometric detection (FPD), microwave-assisted ethylation of the organotin compounds was combined with MAE of the ethylated products. First, MAE of the target compounds from a sediment sample was performed with methanolic 0.5 M ethanoic acid as the extractant. Next, the separated supernatant solution was placed in a 50-mL reaction vessel and the derivatization reagent (sodium tetraethylborate, $NaBEt_4$), extractant (isooctane) and a certain volume of artificial seawater were added. Then the mixture was

exposed to a focused microwave field. The results showed that at volumes lower than 20 mL, quantitative recoveries were obtained with irradiation for 3 min at a microwave power of 70 W for all the compounds except monobutyltin (MBT), for which the recovery was close to 100% following a microwave irradiation for 10 min. The conventional process is also a multistage operation. The ethylation involves 30 min of magnetic stirring followed by extraction of the ethylation products. For the simultaneous extraction–derivatization reaction, the kinetics of the two processes were studied. Ethylation is a nucleophilic substitution, and the extraction is transfer of the derivatized analytes to the organic phase. It was demonstrated that the ethylation was apparently faster than the transfer process, and could be completed within 5 min if the reaction product was removed from the reaction medium or the phases were homogenized. Therefore, extraction does not affect derivatization in this case.

For the speciation analysis of organotin compounds in biomaterials, Pereiro et al.[102] developed an interesting microwave-assisted method by which sample decomposition, extraction, and derivatization of organotin compounds could be carried out simultaneously in a single reactor. Acetic acid was selected as the reaction medium, $NaBEt_4$ as the derivatization reagent, and nonane as the extractant. The reactions were conducted in a focused microwave field with 40 W power for 3 min to reach a temperature of 130 °C. It was found that ethyl derivatives of mono-, di-, and triorganotins were quantitatively detected in the supernatant organic phase. Furthermore, the new method was validated by analyzing a certified reference material (fish tissue, NIES11). The kinetics of simultaneous extraction–derivatization reaction were also investigated. Thus the hours-long multistep sample preparation procedure may be replaced by a one-step integrated method taking only 3 min.

Rodriguez et al.[103] also reported a speciation analysis of organotin compounds in marine biomaterials via microwave-assisted sample preparation using a closed-vessel microwave unit. Tetramethylammonium hydroxide was used as the reaction medium, and the pH of the reaction system was adjusted to 5. $NaBEt_4$ was used as the derivatization reagent, and isooctane as the extractant. This caused the simultaneous alkaline decomposition of the sample, the derivatization of the analytes (organotins) and extraction of the derivatization products. This study also included an investigation of the stability of organotin compounds on exposure to microwaves.

Llompart et al.[104] described an in situ MAE and derivatization for sample preparation to determine phenol and methylphenol isomers in soils. The sample, to which small quantities of acetic anhydride and pyridine had been added in order to catalyse the acetylation process, was immersed in hexane in a closed vessel. Microwave irradiation parameters and other conditions concerning the method were optimized using a factorial design approach. Compared with ultrasonic extraction, the microwave-assisted method gave superior recoveries (about two-fold) and greater precision, in addition to shorter extraction times. The analytes extracted in the hexane phase could be directly analyzed on a GC/MS system without preliminary clean-up or concentration steps.

6 MICROWAVE-ASSISTED SAPONIFICATION AND MICROWAVE-ASSISTED DECOMPOSITION

There have been many applications of MAS or hydrolysis. Microwave energy was used by Chiou and Wang[105] for peptide and protein hydrolysis without significant degradation of the analytes. Tatar et al.[106] also described a microwave hydrolysis system to determine the amino acid composition of protein. Arai and Kakishita[107] reported the manufacture of soap from olive oil and the saponification of $PhCO_2Me$ by microwave heating. Rapid acid hydrolyses of albumin[108] and benzodiazepines[109] were investigated by Morales-Rubio et al. Taketomi et al.[110] established a microwave-mediated saponification of galactosylceramide (cerobroside) and galactosylceramide I^3-sulfate (sulfide) to prepare their lyso-compounds. Moreover, Perez and Haswell[111] developed a flow injection analysis (FIA) method with online MAS of vitamin A to retinol; Young[44] reported a simultaneous MAE and saponification to isolate the fungal metabolite ergosterol from various samples and the fatty acids from spores for their determination. Recently, Pineiro-Avila et al.[19] established a MAS of animal grease for cholesterol determination.

MAS also has applications in organic environmental analysis. Tseng et al.[89] developed a method to detect inorganic mercury and methylmercury in biological samples by MAS coupled with hydride generation, cryofocusing and atomic absorption spectroscopy (AAS) determination. Saponification was performed in tetramethylammonium hydroxide or methanolic KOH solution with microwave irradiation of 40–60 W for only 2–4 min, which was much faster than previously reported methods. This new method was validated by the analysis of four biological certified reference materials, CRM 463, DORM-1, TORT-1 and Tuna fish 2. Recently, Xiong et al.[21] reported a MAS of mussels for PCB determination using a closed-vessel microwave system. A 15-g sample in 30 mL of methanolic KOH solution could be completely saponified in less than 2 min without affecting the PCB analytes. For the speciation of

butyltin compounds in biomaterials, Szpunar et al.[112] used saponification of the sample in tetramethylammonium hydroxide in a low-power microwave field. The biomaterial could be dissolved in less than 5 min, leaving the organotin moiety intact. In addition, as mentioned in section 5, MAS was also studied by Rodriguez et al.[103] for the speciation of butyltin compounds in marine biomaterials. There have been several reports of the use of similar methods for the speciation of other organotin compounds.[113–115]

It is important to distinguish between microwave-assisted decomposition and microwave-assisted digestion (wet ashing) for elemental analysis. In this article, microwave-assisted decomposition for organic environmental analysis refers to the selective decomposition of the sample matrix leaving the target analytes unchanged, whereas in microwave-assisted digestion (wet ashing) the whole sample is broken down.

When gas chromatography/electron capture detection (GC/ECD) is employed for determining PCBs in real-world samples, the co-existing OCPs, such as benzene hexachloride (BHC) and DDT (1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane) often interfere with the determination of the target analytes. Xiong et al.[21,116,117] have developed a microwave-assisted decomposition–extraction method for soil/sediment sample preparation and a MAS–decomposition–extraction method which addresses this problem. Methanolic 1 M KOH solution was selected as the reaction medium and the reaction conditions are optimized so that BHC, *o*,*p*-DDT, *p*,*p*-DDT and *p*,*p*-DDD (1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane) are completely decomposed after microwave heating for 2 min. Although dieldrin, aldrin and *p*,*p*-DDE (1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene) are only partly degraded under these conditions, most of their decomposition products and dieldrin itself can be eliminated with an additional rinse using concentrated H_2SO_4.

In some publications,[20,102] microwave-assisted acidic decomposition of biomaterial samples for the speciation of organometallic compounds is reported. Generally, acetic acid is chosen because, compared with hydrochloric acid, it has a higher boiling point, lower acidity (and thus better compatibility with derivatization–extraction) and neutral behavior towards the carbon–metal bond.[102] According to these reports, microwave-assisted acidic decomposition, actually acidic hydrolysis, may be carried out rapidly and to completion.

7 CONCLUSIONS

For sample preparation in organic environmental analysis, a number of published reports have demonstrated that MAE possesses significant advantages over conventional methods such as Soxhlet and sonication extractions. These advantages include increased recoveries and great savings of time, energy and the quantity of organic solvents consumed. Compared with SFE, MAE generally also has a higher efficiency and wider field of application. Similarly, MAD, MAS, microwave-assisted decomposition, FMASE and microwave-assisted headspace analysis all show significant benefits over the earlier methods. Therefore, it can be predicted that in the near future, more and more laboratories will replace the conventional methods with these newly developed techniques, and they will become routine tools for sample preparation in organic environmental analysis.

However, there is still a need for further developments. In particular:

- microwave instruments, especially the closed vessel systems, need to be more adaptable to automation, making on-line preparation/determination for organic environmental analysis more readily achievable
- to minimize the use of organic solvents, further development of cheap, less toxic aqueous systems for microwave-assisted processes is required
- simultaneous application of several microwave-assisted techniques may further increase the selectivity for isolating target analytes
- the field of application for microwave-assisted techniques for sample preparation in organic environmental analysis may be greatly widened by using them in conjunction with other methods of sample preparation.

Microwave-enhanced solvent extraction is a relatively new approach for the extraction of organic pollutants from solid environmental matrices. This approach uses microwave technology to heat organic solvent in contact with the sample in either a sealed (pressurized) or open (atmospheric) vessel. The major advantage of this approach over conventional extraction procedures, such as Soxhlet extraction, is the speed of the process. As well as the principles of microwave heating, the article also describes the instrumentation required to effect the extraction process. Finally, selected applications of microwave-enhanced solvent extraction are described. Applications are divided into extraction from solid matrices and extraction from aqueous matrices. The specific analytes covered include the extraction of polycyclic aromatic hydrocarbons (PAHs), hydrocarbons, polychlorinated biphenyls (PCBs), pesticides and phenols from solid matrices; direct extraction of chlorinated benzenes from aqueous matrices; microwave elution of a range of analytes from solid-phase extraction (SPE) media and, finally, volatile compounds, e.g. benzene, toluene, ethylbenzene and xylenes (BTEX) from aqueous samples. Finally, some recommended operating conditions for the extraction of analytes from solid matrices using pressurized microwave-assisted extraction (MAE) are provided.

1 INTRODUCTION TO ENVIRONMENTAL ORGANIC SAMPLE PREPARATION

Analysis of organic pollutants in the environment is necessary because of past or present industrial activity, accidental spillage and deliberate (unlicensed) disposal, all of which can have ecotoxicological effects on living organisms. In order to assess the potential damage, remediate known sites or simply to have an early warning of potential problems requires environmental measurement of the levels of organic pollutants. Organic pollutants are located in all compartments of the environment. Thus, typically we refer to pollution in terms of natural waters (e.g. lakes, rivers, groundwater, potable water), solid or semisolid matrices (e.g. soil, sludge, vegetation) and the atmosphere (e.g. air). In this article we are concerned principally with solid-type matrices, although some attention is given to aqueous sample preparation. A recently published book discusses the different types of sample preparation approaches for both liquid and solid samples of environmental origin.[1]

Preparation of solid samples for organic analysis can traditionally be subdivided into two classes, with heating and without heating. In the latter case, we refer to the use of a shake flask, while in the former Soxhlet extraction is used. Shake-flask extraction involves placing a solid sample into a container together with an organic solvent and agitating, either manually or by the use of a laboratory shaker, for a given period of time. Subsequently the organic solvent containing the extract is removed via filtration, a separating funnel or decanting. Soxhlet extraction involves refluxing warm organic solvent through the sample repeatedly for several hours. This is achieved by heating organic solvent contained in a round-bottomed flask, on an isomantle. The vaporized solvent is then condensed, via a water-cooled condenser, and falls into a thimble containing sample. This in turn returns to the round-bottomed flask. The whole process is repeated frequently until the preset extraction time is reached. As the extracted analyte will normally have a higher boiling point than the solvent it is preferentially retained in the flask and fresh solvent recirculates. This ensures that only fresh solvent is used to extract the analyte from the sample in the thimble. A disadvantage of this approach is that the organic solvent is below its boiling point when it passes through the sample contained in the thimble. In practice this is not

Encyclopedia of Analytical Chemistry

necessarily a problem as Soxhlet extraction is normally done over long time periods i.e. 6, 12, 18, or 24 h.

More recently, alternative approaches have become available. In addition to the shake-flask approach it is possible to agitate the sample using a sonic bath or sonic probe. Modifications of Soxhlet extraction have appeared which offer some degree of solvent reduction and automation, e.g. Soxtec. Perhaps the biggest changes have occurred in terms of the instrumentation available for extraction of pollutants from solids. The 1980s saw the arrival of commercial apparatus for supercritical-fluid extraction (SFE), while the early 1990s heralded the commercial availability of MAE closely followed in 1995 by accelerated solvent extraction (ASE).

This article is concerned with the use of microwave technology for the extraction of organic pollutants from environmental (solid and liquid) matrices. While the first papers on the subject were published in 1986[2] using a domestic microwave oven, this article only considers the work published in the 1990s when commercial systems became available.

2 PRINCIPLES OF MICROWAVE HEATING FOR ORGANIC SOLVENTS

Microwaves are high-frequency electromagnetic radiation. The most commonly used frequency of operation of microwaves is 2.45 GHz. The choice of solvent for MAE is essential. The solvent must be able to absorb microwave radiation and pass it on in the form of heat to other molecules in the system. The ability to pass on this energy is measured in terms of the dissipation factor ($\tan\delta$), see Equation (1):

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'} \qquad (1)$$

where, ε'' is the dielectric loss (a measure of the efficiency of conversion of microwave energy into heat energy) and ε' is the dielectric constant (a measure of the polarizability of a molecule in an electric field).

This polarizability is achieved by the reorientation of permanent dipoles by the applied electric field. This means that under microwave conditions, a polarized molecule will rotate to align itself with the electric field at a rate of approximately 10^9 times per second. This results in very rapid heating. An estimate of the ability of the microwave oven to couple to any molecule can be obtained by considering its ε' values (Table 1). It is not suprising to find therefore that polar solvents, such as water, acetone and methanol all readily absorb microwaves and hence are heated up when subjected to microwave radiation, while nonpolar solvents, such as hexane and toluene, do not heat up when they are subjected to microwave irradiation. In addition, since the extraction process typically takes place in a closed vessel, the solvent chosen can be heated well above its normal boiling point (Table 1). This will reduce the time required for the extraction process.

Table 1 Solvent properties for MAE

Solvent	Dielectric constant[a]	Boiling point (°C)[b]	Closed-vessel temperature (°C) at 175 psig[b,c]
Hexane	1.89	68.7	NH
DCM[d]		39.8	140
Acetone	20.7	56.2	164
Methanol	32.63	64.7	151
Acetonitrile	37.5	81.6	194
Acetone : hexane (1 : 1 v/v)	–	52	156

NH – no heating in microwave.

[c] Pounds per square inch gauge.
[d] Dichloromethane.

3 APPARATUS FOR MICROWAVE-ENHANCED SOLVENT EXTRACTION

Two types of microwave heating systems are commercially available: an open-vessel (atmospheric) system and a closed-vessel (pressurized) system. In the open-style system, individual sample vessels are heated sequentially. A typical commercial system is the Soxwave from Prolabo Ltd., France. A schematic diagram of the atmospheric-MAE system is shown in Figure 1. This system operates at percentage power increments from 0–100%, corresponding to a maximum of 300 W. These power increments can be operated in stages and for various time intervals (up to 9 h). The sample and solvent are introduced into

Figure 1 Schematic diagram of an atmospheric MAE system.

a glass container which is fitted with either an air or a water condenser to prevent loss of volatiles and solvent. The sample container is located within a protective glass sheath. The organic solvent is then heated, by means of microwave energy, and refluxed through the sample.

A common commercial closed system (pressurized-MAE) is the MES-1000 microwave solvent extraction system (CEM Corp., USA). A schematic diagram of the pressurized-MAE system is shown in Figure 2. (Note: nine extraction vessels only are shown.) This system allows up to 12 extraction vessels to be irradiated simultaneously, in 1% increments, up to 950 W of microwave energy at 100% power. This system has in-built safety features, such as an audible alarm for the detection of an unexpected release of flammable and toxic organic solvent, a Teflon-lined microwave cavity, and an exhaust fan which continues to operate in the event of a solvent escape. Microwave conditions can be monitored via in situ pressure and temperature sensors (located within a single extraction vessel only). Pressure is measured using a water manometer that allows readings of up to 200 psi (1 psi = 6894.76 Pa) to be made. The temperature probe, a fiber optic with a phosphor sensor, allows extraction temperatures to be selected from 20–200 °C in 1 °C increments. Samples are placed into Teflon perfluoroalkoxy (PFA) vessels (100 mL capacity) which are themselves located within a polyetherimide protective casing (bodies and caps). Each extraction vessel contains a rupture membrane that is designed to fail at elevated pressure (200 psi). Each extraction vessel (up to 12) is located in a carousel which rotates through 180° during microwave operation. In the center of the carousel is an expansion chamber which is connected to each extraction vessel, and which acts to contain escaping vapors in the event of rupture membrane failure.

4 APPLICATIONS OF MICROWAVE-ENHANCED SOLVENT EXTRACTION IN ENVIRONMENTAL ANALYSIS

4.1 Extraction from Solid Matrices

4.1.1 Atmospheric Microwave-enhanced Solvent Extraction

Akhtar and Croteau[5] reported the extraction of sodium salinomycin (CAS 55721-31-8, referred to as salinomycin antibiotic) from finished chicken feed. It is added to the feed at a level of 60 mg kg^{-1}. Salinomycin is used to prevent coccidiosis in broiler chickens. A conventional microwave oven (800 W) was used for the extraction followed by postcolumn derivatization high-performance liquid chromatography (HPLC). The feed (0.6 g) was placed in a polyethylene container and extracted with ethanol (15 mL) and propan-2-ol (2 mL) for 8 s. After irradiation, the organic layer was decanted off and the microwave process repeated twice more. All extracts (three times) were combined, centrifuged and evaporated to dryness. The residue was reconstituted in 10 mL of mobile phase. The results were compared with a conventional approach based on liquid–solid extraction and vortex mixing for 3 min. The same solvent system and volumes were used. The sample extract was treated the same as for the microwave extraction. The results in the finished feed were as follows: 34, 60, 103 and 160 mg kg^{-1} by MAE and 27, 45, 59 and 112 mg kg^{-1} using liquid–solid extraction. The expected values, based on calculation, were 30, 60, 90 and 150 mg kg^{-1}. The authors concluded that MAE shows great potential for the monitoring of veterinary drug and pesticide residues in animal feeds and edible tissues and eggs.

Focused MAE (Maxidigest 350, Prolabo, France) was applied to the extraction of PAHs from reference materials (sediment, soil, air particulates) by Letellier et al.[6] Initial studies were performed on marine sediment (National Institute of Science and Technology (NIST) standard reference material (SRM) 1941a) where it was found that small quantities of organic solvent (30 mL DCM) at short extraction times (10 min) and 30 W microwave power provided good recoveries (average recovery 87% for 13 PAHs) with standard deviations comparable to those obtained using Soxhlet extraction (2 × 250 mL DCM for 48 h). This approach was then applied to two other reference samples: soil (Community Bureau of Reference (BCR), certified reference material (CRM) 524) and air particulate/urban dust (NIST SRM 1649a). The results, compared to certificate values, were in good agreement (average recovery 97% with a relative standard deviation (RSD) of 6.4%, $n = 18$). The procedure was also applied to two sediment samples (industrial harbour marine sediment and yatching

Figure 3 Extraction of PAHs from contaminated soil. (Adapted from Saim et al.[7])

harbour sediment). The results, compared to Soxhlet extraction, produced slightly lower recoveries (average recovery 90% with an RSD of 7.9%, $n = 24$). The benefits of this open MAE approach are the speed of analysis, simplicity of operation and safety in use. It is noted however, that the group did not include the most volatile PAHs in their remit, omitting two-ring aromatics, i.e. naphthalene (CAS 91-20-3).

Saim et al.[7] compared the merits of Soxhlet extraction, pressurized-MAE, SFE and ASE with atmospheric-MAE for the extraction of PAHs from native contaminated soils. Atmospheric-MAE was done using a Soxwave-100 system. A 2-g soil sample was irradiated with 70 mL DCM for 20 min at 99% power. The extract was filtered and reduced in volume to 5 mL prior to analysis. The results (Figure 3), for 14 PAHs, show that comparable recoveries are obtainable by all extraction methods. The sum of the 14 PAHs by each extraction technique were as follows: 1623, 1578, 1492, 1544 and 1537 mg kg^{-1} by Soxhlet extraction, pressurized-MAE, atmospheric-MAE, SFE and ASE, respectively. Finally, the individual PAH recoveries were statistically compared with Soxhlet extraction. It was found, at the 95% confidence interval, that the majority of PAH determinations were not significant for MAE (atmospheric and pressurized). The authors concluded however, that the method choice, based on the data presented, still appears to be Soxhlet extraction.

4.1.2 Pressurized Microwave-enhanced Solvent Extraction

Pressurized-MAE is by far the most common approach that has been utilized for the extraction of organic pollutants from solid environmental matrices. Accordingly this section has been subdivided with respect to the analyte of interest.

4.1.2.1 Polycyclic Aromatic Hydrocarbons PAHs are the most commonly studied organic pollutant by MAE. As part of an on-going evaluation of new sample preparation techniques by the United States Environmental Protection Agency (USEPA), especially those that minimize waste solvents, MAE has been evaluated.[8] Using a 1 : 1 hexane : acetone solvent mixture, the influence of extraction temperature (80, 115 and 145 °C) and extraction time (5, 10 and 20 min) on the recovery of PAHs from CRMs was compared with room-temperature extraction using the same solvent and contact time. It

Figure 4 Extraction of PAHs from sediment (NIST SRM 1941a). (Adapted from Lopez-Avila et al.[10])

was found that the average recoveries by MAE for the 17 PAHs studied ranged from 70–75%. The authors concluded that MAE offers reduced extraction time (typically 10 min for extraction and 40 min for cooling, centrifugation and extract concentration) and reduced solvent use (30 mL versus 300 mL for Soxhlet/Soxtec). In addition, up to 12 samples can be extracted simultaneously. This work was extended to incorporate a spiked soil sample with and without ageing.[9] It was noted that recoveries from aged samples decreased, compared to freshly spiked samples. The same group[10] extended this work to compare MAE with Soxhlet, sonication and SFE. Again freshly spiked soil samples were evaluated along with two CRMs. A whole range of compounds were considered (95 compounds in total). It was concluded that MAE gave superior or equivalent results to the other techniques considered. Of the compounds studied, the number of recoveries >80% was 51 by MAE, 50 by Soxhlet, 63 by sonication, and 37 by SFE. As an example, the recoveries of 14 PAHs from a certified sediment sample (SRM 1941a) by the different extraction techniques are shown in Figure 4.

Similarly, Dean et al. have evaluated the effectiveness of MAE for the extraction of PAHs from industrially contaminated soil.[11–13] Initial work considered the robustness of MAE.[11] It was found that acetone was the solvent of choice compared to hexane : acetone (1 : 1) and DCM only. An experimental design approach was used to investigate the dependence of operating variables (temperature, extraction time and solvent volume). These variables were considered between strict operating limits, i.e. temperature, 40–120 °C; extraction time, 5–20 min and solvent volume, 30–50 mL. It was concluded that MAE was independent of the variables considered (and their limits) for the extraction of PAHs from native contaminated soil. The PAH recoveries from the soil by MAE (20 min extraction plus 30 min cooling time using 40 mL acetone) were compared with Soxhlet (extraction for 6 h using DCM), SFE (1 h extraction using 10% methanol-modified CO_2) and ASE (12 min extraction using 25 mL acetone : DCM 1 : 1).[12,13] It was found that MAE compared favorably with SFE and ASE. All techniques gave superior results compared to Soxhlet extraction. The sum of 16 individual PAHs was 422.9, 297.4, 458.0 and 421.0 mg kg^{-1} by MAE, Soxhlet, SFE and ASE, respectively. Solvent choice was considered to be an important variable for extraction of native contaminants.

Certified marine sediments and soil have been extracted by MAE and analyzed for PAHs.[14] The sample (1–5 g) was irradiated with microwave radiation in the presence of 30 mL of hexane : acetone (1 : 1), for 10 min at 115 °C. Recoveries of 14 PAHs from certified soil (standard reference soil (SRS)-103–100) ranged from 67% with an RSD of 22.1% for dibenzo[*ah*]anthracene (CAS 53-70-3) to 111% with an RSD of 10.2% for benzo[*k*]fluoranthene (CAS 207-08-09).

The certified values ranged from 14.2–1924.9 ppm. Similarly, recoveries of 16 PAHs from marine sediments

Figure 5 MAE of PAHs from CRMs. (Adapted from Li et al.[14])

(HS-3, HS-4 and HS-5) ranged from 61% (naphthalene) to 275% (benzo[*k*]fluoranthene) for HS-3; 54% (naphthalene) to 156% (benzo[*k*]fluoranthene) for HS-4; and, 52% (benzo[*a*]pyrene, CAS 50-32-8) to 137% (benzo[*k*]fluoranthene) for HS-5. Average recoveries, based on 16 individual PAHs, for HS-3, HS-4 and HS-5 were 103, 88 and 79%, respectively. In addition, a further marine sediment was also analyzed (SRM 1941) for 15 PAHs. Recoveries ranged from 72.4% (perylene) to 130.2% (benz[*k*]fluoranthene) with an average recovery, based on 15 individual PAHs, of 99%. The results for the extraction of PAHs from certified reference samples are summarized in Figure 5.

An evaluation of extraction solvent for the MAE of PAHs from sediment samples has been reported.[15] Three solvent systems were evaluated: acetone : hexane (1 : 1), hexane : water and toluene : water. The acetone : hexane mixture was included in this study because it has been by far the most studied extraction solvent system for MAE. For the other two solvent systems, water was added at 10% (v/v) in all cases. MAE was done by placing the sample (2–10 g) and solvent mixture in a hermetically sealed polytetrafluoroethylene (PTFE) reactor and then irradiating at 660 W power for 6 min. After cooling, the sample container was opened and 8 g of sodium sulfate added to dry the organic phase. All extracts were then evaporated to dryness and dissolved in 2 mL hexane. Copper wire was then added to remove sulfur and the solution was finally passed through a microcolumn of activated Florisil and eluted with 30 mL of DCM : hexane (70 : 30 v/v). Finally, the extract was evaporated to dryness and dissolved in 200 µL solvent. Final extracts were quantified using gas chromatography (GC) with either flame ionization detection (FID) or mass selective detection (MSD). The recoveries, compared to Soxtec extraction, for a marine sediment were in agreement (average recoveries were 101, 99 and 102% using acetone : hexane, hexane : water and toluene : water, respectively). The automated Soxtec extraction was based on 2 g sample, 60 mL hexane : acetone (1 : 1 v/v) for 1 h sample immersion followed by 1 h of heating under reflux.

4.1.2.2 Hydrocarbons A method was developed for the quantitative extraction of gasoline- and diesel-range petroleum hydrocarbons from soil and marine sediment samples.[16] Microwave operating parameters were evaluated using a two-level orthogonal array design. The operating parameters varied were as follows: solvent (DCM and acetone), temperature (80 and 115 °C) and extraction time (5 and 15 min). It was found that the optimum conditions were: 30 mL of acetone at a temperature of 115 °C and heated for 5–15 min. The effects of

wetting the sample on the recoveries of 14 hydrocarbons were investigated using spiked soil and marine sediment. Under dry conditions recoveries ranged from 60.0 to 88.3% with an RSD of 3.5–10.1% for marine sediment and from 60.4 to 89.6% with an RSD of 3.7–13.5% for soil. Under wet conditions (10% w/w) the recoveries improved; 80.5–100% with an RSD of 2.0–7.9% for marine sediment and 80.2–100.4% with an RSD of 2.3–7.4% for soil. The method was then applied to a range of local (Singapore) sediment and soil samples. It was concluded that the level of hydrocarbon contamination was low in the areas sampled.

MAE of linear hydrocarbons (C_{16}–C_{32}) from a lyophilized sediment sample using a mixture of toluene and water (90 : 10% v/v) is proposed.[15] For further details of the experimental procedure, see section 4.1.2.1 on PAHs. The authors reported that, provided the microwave power was maintained above 66%, quantitative recoveries could be obtained irrespective of the extraction time (3–12 min). Similarly, maintaining a sample : toluene ratio greater than 1 : 2 provided quantitative recoveries. Extraction yields from the native sediment samples were assessed by comparison with Soxhlet extraction.

4.1.2.3 Polychlorinated Biphenyls PCBs have been extracted from a range of CRMs (marine sediment and soils) using MAE.[9] The following proven conditions were used: solvent, 30 mL of hexane : acetone (1 : 1 v/v); temperature 115 °C; and extraction time 10 min. The recoveries compared with certificate values were as follows: Arochlor 1254 from marine sediment HS-1 and HS-2, 93.2 and 76.7%, respectively; Arochlor 1260 from Environmental Research Associates (ERA) soil (lot number 9801), 89.9%; and Arochlor 1248 from Superfund site soils, 102, 157, 86.8 and 75.3%. Values for the Superfund site soils were based on those obtained by an independent laboratory using Soxhlet extraction and gas chromatography/electron capture detection (GC/ECD). The same certified reference samples (HS-1, HS-2 and the ERA soil) were analyzed by Lopez-Avila et al.[17] to compare the method of detection (GC/ECD or ELISA (enzyme-linked immunosorbent assay) of the PCBs after MAE. It was found that the results closest to the certificate values were obtained using GC/ECD. However, it was concluded that the ELISA approach was more rapid. A batch of 10 samples could be prepared and analyzed in approximately 1 h.

4.1.2.4 Pesticides Sample ageing, either artificially or by natural weathering, is an important factor to consider when evaluating any new extraction technique. However, it is unfortunate to note that most published methods for MAE are based on freshly spiked samples. Onuska and Terry[18] aged a slurry spiked air-dried sediment for at least one month prior to MAE extraction of organochlorine pesticides (OCP). It was found that the optimum extraction conditions consisted of an extraction solvent of isooctane : acetonitrile (1 : 1 v/v), a mimimum water content of the sample of 15% and an extraction time of >3 min. The results for the extraction of 15 OCPs from a spiked sediment sample (at spiking levels between 50 and 250 $\mu g\,kg^{-1}$) were good, the minimum recovery was 74% (3% RSD) for *p*,*p*′-DDE (1,1′-(2,2-dichloroethylenylidene)-bis(4-chlorobenzene) or 2,2-bis(4-chlorophenyl)-1,1-dichloroethylene) (CAS 72-55-9) while the best recovery was 95.3% (3.9% RSD) for methoxychlor (CAS 72-43-5) ($n = 5$).

The nature of the MAE process is such that heating can only occur if the solvent has a permanent dipole moment. As an alternative to the conventional approach, Hummert et al.[19] utilized a microwave transformer (Weflon®, an inert material based on carbon-containing teflon) to extract OCPs from seal blubber using a nonpolar solvent, e.g. hexane. It was experimentally determined that the best approach for MAE was to operate with seven extraction cycles (30 s duration at full power). Average recoveries for the seven organochlorine compounds from seal blubber were 96.9 ± 0.5%.

Extraction of a fungicide, hexaconazole, which had been weathered over periods of time up to one year was reported from two characterized soils.[20] The soils, which had been collected at various times after application of the fungicide, were air dried for 48 h and sieved through a 2–3.5 mm sieve prior to storage at −18 °C. The levels of hexaconazole in the two soil types were assessed using Soxhlet extraction, MAE, SFE and ASE. Extraction with microwave energy was done by irradiating a 5-g sample with 30 mL of acetone at 115 °C for 15 min. The soil extract was then precleaned using C_{18} SPE media and after elution with methanol the volume reduced to 1 mL. The results for the sandy clay soil (organic matter, 1.5%) were comparable by all extraction techniques (Figure 6). For example, the 52-week aged sample gave recoveries of 0.08, 0.072, 0.073 and 0.070 $mg\,kg^{-1}$ by Soxhlet, SFE, MAE and ASE, respectively. However, this was not

Figure 6 Extraction of hexaconazole from aged soils: sandy clay soil (organic matter, 1.5%). (Adapted from Frost et al.[20])

Figure 7 Extraction of hexaconazole from aged soils: sandy loam soil (organic matter, 5.7%). (Adapted from Frost et al.[20])

the case for the sandy loam soil (organic matter, 5.7%) where recoveries for the aged sample (52 weeks) were 0.07, 0.034, 0.035 and 0.093 by Soxhlet, SFE, MAE and ASE, respectively (Figure 7). It was concluded that ASE was unaffected by analyte–matrix interactions, providing good recoveries for all sample types.

4.1.2.5 Phenols The continued interest by USEPA in new sample preparation techniques has focused on a wide range of compounds including phenols.[21] In this work, 16 phenolic compounds were extracted (30 mL acetone : hexane (1 : 1 v/v), at a temperature of 115 °C for 10 min) from freshly spiked clay soil, topsoil, sand, organic compost and topsoil with 5% humic acid. The recoveries of the phenolic compounds, spiked at the $50\,\mu g\,g^{-1}$ level, were determined. It was found that the majority of the samples analyzed gave recoveries above 70%. It was however noted, that 2,4-dinitrophenol (CAS 51-28-5) and 4,6-dinitro-2-methylphenol (CAS 534-52-1) may have degraded or become irreversibly adsorbed to the soil-type matrices. The method was then applied to the extraction of six phenols from a certified soil (ERA soil, lot number 330). The results were compared with Soxhlet and sonication extraction. The average recoveries for the six phenols ranged between 71%, 52% and 57% for MAE, Soxhlet and sonication, respectively. The most precise results were also obtained by MAE.

Llompart et al.[22] have utilized a central composite design for the MAE of phenol (CAS 108-95-2) and methylphenol isomers from spiked soils that have been aged for 25 days to simulate weathering processes. The following MAE operating variables were optimized: temperature (70–130 °C); solvent type (acetone–hexane mixtures); and solvent volume (15–50 mL). The extraction time was maintained at 10 min and the amount of sample was fixed at 5 g. At the 95% confidence interval, temperature was significant for all four phenols (phenol, *o*-cresol (CAS 95-48-7), *m*-cresol (CAS 108-39-4) and *p*-cresol (CAS 106-44-5)), while the acetone : hexane ratio and solvent volume were found to be significant in some cases only. Quantitative recoveries from the spiked and aged soil samples, were obtained using 10 mL of acetone : hexane (80 : 20 v/v) at 130 °C. Typical recoveries ranged from 94.5–104.4% with an RSD of 6.1–9.9%. The same group[23] developed a simultaneous MAE-derivatization procedure for phenol and methylphenol isomers. Samples (aged spiked and real soils) were irradiated in a closed vessel while immersed in hexane that had been previously doped with acetic anhydride and pyridine. The procedure was optimized using a factorial design. The developed method was applied to a soil sample from a coke plant known to be highly contaminated. The results obtained by this approach were as follows: $1.5\,\mu g\,g^{-1}$ for *o*- and *p*-cresol, $4.4\,\mu g\,g^{-1}$ for *m*-cresol and $7\,\mu g\,g^{-1}$ for phenol; results obtained using a sonic probe were approximately half the values reported.

4.2 Extraction from Aqueous Matrices

4.2.1 Direct Extraction

A novel approach for the microwave oven has been its use to extract chlorinated benzenes directly from water samples.[24] An aqueous sample was placed in a screw-capped container located in the microwave oven. Through the cap of the container were inserted a helium purge line and an exhaust line. The exhaust line led to a trap which was cooled in an ice bath. This dynamic extraction procedure was completed as follows: aqueous sample (1 L) containing 20 g of salt was purged with helium for 20 min whilst operating the microwave oven at full power for 7 min. The extract was collected in the cooled trap. Excess water was removed by passing the extract through a microcolumn of anhydrous sodium sulfate; the column was eluted with 2×1 mL of hexane and concentrated under a stream of nitrogen to 2 mL. Further cleanup was necessary using a Florisil microcolumn prior to analysis. This approach was compared with the traditional approach of liquid–liquid extraction and found to compare favorably at the nanogram per liter level. Average recoveries for 10 chlorinated benzenes spiked into water at the $1\,ng\,L^{-1}$ level were 63% by a microwave-assisted process (MAP) and 69% by liquid–liquid extraction, while at the $10\,ng\,L^{-1}$ level the average recoveries increased to 93% by MAP and 98% by liquid–liquid extraction. The same group[25] applied the approach to the extraction of PCBs from 500 mL of water. Recoveries of the spiked congeners, at two levels 85.5 and $175\,pg\,L^{-1}$, in organic-free water were in the range 68–85%. The technique was then applied to Hamilton Harbour water and the results were compared with liquid–liquid extraction. Average recoveries ($n = 7$) of PCB 209 by MAP were 90.9% compared with 80.6% by liquid–liquid extraction at a concentration of approximately $20\,pg\,L^{-1}$.

4.2.2 Solid-phase Extraction/Microwave Solvent Elution

MAE has been combined with SPE for the extraction of pollutants from aqueous samples.[26] The procedure is as follows: analytes of interest are retained on a C_{18} membrane disk (Empore), the disk is then rolled up and transferred into the closed PTFE-lined vessels of the MAE. Elution is achieved by placing organic solvent into the extraction vessel and irradiating the disk. The approach has been applied to a range of compounds, including OCPs, PCBs, PAHs, phthalate esters, organophosphorus pesticides (OPPs), fungicides, herbicides and insecticides, in aqueous solution.[26] The operating variables have been optimized. The variables considered were: elution solvent (acetone and DCM); temperature (80, 100 and 120 °C); and extraction time (1, 3, 5 and 10 mins) at 50% power. The optimum conditions for microwave elution were acetone at a temperature of 100 °C for 7 min. Excellent results compared to liquid–liquid extraction, were obtained for PAHs and phthalates (spiked at 2 μg L^{-1}), OCPs (spiked at levels between 0.1–0.2 μg L^{-1}), PCBs (spiked at 0.5 μg L^{-1}) and OPPs, fungicides, insecticides and herbicides (spiked at levels between 1–2 μg L^{-1}) in either reagent water or seawater.

4.2.3 Gas-phase Microwave-assisted Extraction

The liberation of volatile organic compounds (VOCs) from water samples by microwave energy has been described by Pare et al.[27] The aqueous sample is heated via a microwave oven, vaporizing VOCs into the headspace of the sample. By utilizing a conventional headspace sampler the VOCs are introduced directly into GC with FID. This approach was compared with a conventional 30 min static headspace sampling apparatus and the results obtained were favorable. It was noted, however, that the microwave approach gave higher detector responses, with better precision and in a shorter timescale than the conventional approach. The approach was subsequently extended to a range of volatile compounds including simple aromatics, i.e. benzene (CAS 71-43-2), toluene (CAS 108-88-3), ethylbenzene (CAS 100-41-4), *o*-, *m*- and *p*-xylene (CAS 1330-20-7), propylbenzene (CAS 103-65-1) and butylbenzene (CAS 104-51-8), as well as alkanes, i.e. C_8, C_{10}, C_{12} and C_{13}.[28] In each case, a sensitivity enhancement was noted for the microwave approach (average enhancement factor was 4.4).

5 CONCLUSIONS

The use and application of MAE continues to expand. However, as the reader will be aware after reading this article, the diversity of operating conditions and solvent choice suggested by others, merely adds to the difficulty in accepting MAE in the laboratory. To assist the reader in this choice Table 2 contains guidelines for MAE method development. As pressurized-MAE is the most common approach, details for this mode of operation only are provided. The parameters shown in Table 2 are based on the use of a microwave system capable of delivering a minimum power of 900 W. Ideally, the microwave system should be equipped with the following safety features: a fan and appropriate ducting to allow ventilation of the cavity in the event of an organic vapor release; a solvent sensor that automatically shuts off the microwave source in the event of an organic solvent leakage (minimizing the risk of fire) and extraction vessels that will automatically vent into a solvent collection system at a preset pressure (to minimize the risk of explosion).

Table 2 Recommendations for pressurized-MAE

Variable	Operating condition
Temperature	>115 °C but <145 °C.
Pressure	<200 psi NOTE: Extraction vessels should have a safety feature, e.g. rupture membrane, that prevents this pressure being exceeded.
Microwave power	100%
Extraction time (time at parameter)	>5 min but <20 min. NOTE: The longer time is recommended if 12 vessels are to be extracted simultaneously.
Extraction solvent volume	30–45 mL per 2–5 g of sample
Extraction solvent	Hexane–acetone (1 : 1 v/v) has been the most commonly used. Other solvents also appear to be satisfactory, e.g. acetone.

After a brief historical survey of the role of neutron activation analysis (NAA) in environmental analysis there follows a section on the main types of NAA and their application to environmental problems and a table of ideal sensitivities is given. The rest of the article deals with NAA as it is applied to the main divisions of the environment. Each of these sections includes a short summary of the sampling requirements suitable for NAA. Section 3 deals with its application to biological samples and includes a brief discussion on standard reference materials (SRMs) in NAA. Applications to various types of biological material are discussed, ending with a survey of biomonitoring using NAA. The next section (the longest) is the analysis of water by NAA. This is mainly based on the preconcentration and postirradiation procedures currently used for the major types of water (seawater, surface water and underground water). A table of element concentrations in seawater and surface water illustrates the low limits of detection required to determine many trace elements by instrumental neutron activation analysis (INAA). Applications are discussed in the main body of the text. There then follows a section on the use of NAA in air particulate analysis for trace elements. The importance of PM10s (particles with aerodynamic diameter less than 10 μm) to human health and the reasons for concentrating on the analysis of these particles by NAA is discussed. Having discussed the main areas of NAA used there follows an application section. Large-scale biomonitoring procedures are outlined, particularly those involving plant materials. The final section on major environmental divisions covers the use of NAA in analysis of soils and sediments together with the analysis of coal. This latter topic also includes on-line analysis of coal using isotope sources. Finally, there is a discussion of speciation and the function of NAA in environmental speciation, particularly atmospheric and aqueous speciation analysis.

1 INTRODUCTION

NAA is usually said to have begun with the work of Hevesy and Levi[1,2] on the analysis of the lanthanides, although it was only in their second paper that they described the determination of an element (Eu) by NAA. Having only weak neutron sources meant that the method remained essentially a curiosity. Virtually no further developments of the technique occurred until after the end of the Second World War and the availability of far higher neutron intensities from newly constructed nuclear reactors. These allowed analyses of samples at a sensitivity comparable to, or even better than, most other analytical techniques then available. This fact, combined with its inherent multielement capability, capacity to

Encyclopedia of Analytical Chemistry

analyze a large number of samples, ease of sample preparation and freedom from contamination following irradiation meant that it had many distinct advantages over comparable techniques such as atomic absorption spectroscopy (AAS), flame emission spectroscopy (FES), mass spectrometry (MS) and polarography. Despite some disadvantages, such as the availability of a large expensive reactor facility and its relative insensitivity for some elements of importance in toxicology and pollution it rapidly became the choice for multielement analysis.

Even by 1968, however, Meinke commented that NAA was not a panacea for all analytical problems and that it was best considered as only one of a number of analytical techniques which can complement each other. Thus, the best way of viewing the solution to an analytical problem is to regard the various techniques available as complementary and not competitive. No one technique (not even ICPMS (Inductively Coupled Plasma Mass Spectrometry)) is ''best''. Centers that provide a variety of analytical techniques are probably the ones that will provide the most accurate and wide-ranging analyses, particularly of environmental samples. On the other hand, the development of ICPMS systems with the provision for direct analysis of solids (using electrothermal evaporation, etc.) might see this technique assuming a dominant position.

Since the late 1970s a number of significant improvements have occurred, such as the routine use of epithermal neutron activation analysis (ENAA) and cyclic NAA, which have overcome some of the aforementioned problems for some important elements. NAA, however, is now regarded as a ''mature'' technique, i.e. one which has reached a plateau as far as new developments in the techniques expected in the future.

Several books and reviews on NAA have been published detailing the technique and its applications but few deal exclusively, or even substantially, with environmental applications. Probably the best of these is the two-volume book edited by Alfassi[3] which covers the techniques and methodology in volume I and environmental applications in volume II. An older but still very useful book which deals more with radioanalytical NAA in environmental analysis is that by Das et al.[4] as well as a similar book by Tolgyessy and Kyrs.[5] There is a review article by Eisenbud[6] of the whole field and one by Ehmann and Vance[7] covers advances in NAA to 1989, including environmental analysis. Other good review articles have appeared on the role of NAA in air particulate analysis.[8,9] Other areas of environmental research have not been so well reviewed. Starting in 1986, Ehmann et al. periodically published literature surveys covering all fields of NAA, including applications in environmental analysis, until 1994.[10–14] Yates published a similar survey in 1997.[15]

2 SCOPE OF NEUTRON ACTIVATION ANALYSIS

The actual technique and instrumentation used in NAA has been discussed in articles **Chemical Analysis by Nuclear Methods: Introduction**, **Instrumental Neutron Activation Analysis** and **Nuclear Detection Methods and Instrumentation**. NAA is usually subdivided into (1) INAA, which is nondestructive and is purely instrumental and (2) radiochemical neutron activation analysis (RNAA), which involves dissolution of the sample and some more or less complex chemical separations, usually postirradiation. RNAA produces the ultimate in sensitivity limits for the method and is essential for determining certain elements such as P and Tl in any matrix, or particular elements in specific matrices, owing to inherent interference in the γ-ray spectrum. The penalty to be paid for this improvement in sensitivity and precision is that of complexity and time for analysis. INAA is a much simpler technique and geared to processing quite large numbers of samples in a relatively automated way while still retaining good accuracy and precision. It is, therefore, the method usually chosen, if possible. Probably, still the most widely used method of NAA is the comparator method, using several single element standards or a single, multielement standard. The development of single element comparator methods (especially the k_0 method), has reduced analysis time and improved accuracy.

INAA can be further subdivided into thermal (and epithermal) NAA and fast neutron activation analysis (FNAA). Thermal NAA takes advantage of the high intensity of neutrons available from the thermalization of fission neutrons in a nuclear reactor and the large thermal neutron cross-sections for most isotopes. This makes the technique suitable for trace element determinations which is its major application in chemical analysis. INAA usually refers to its use with reactor thermal neutrons. Sensitivities for element determinations by INAA are matrix dependent but some calculated values for interference-free sensitivities are given in Table 1.

An additional factor in environmental research is the fact that the matrix elements C, H, N and O produce no significant activity and so virtually no interference problems. Other matrix elements such as Mg, Al, Si and Ca give rise to fairly short-lived activities that may only interfere with a few short-lived trace element radioisotopes.

FNAA usually refers to irradiations with neutrons with the specific energy of 14.7 MeV. FNAA is not usually regarded as a trace element technique owing to the much lower fluxes generally available and the generally much smaller reaction cross-sections. The major exception to this rule is for the determination of oxygen

Table 1 Calculated best INAA detection sensitivities for some environmentally important elements with γ-emitting nuclides, in the absence of any interfering activities[a]

[b] Sensitivities based on the following parameters: $\phi_{th} = 10^{17}\,nm^{-2}\,s^{-1}$, irradiation time = 5 h max., decay time = 0, count time = 100 min max., 40 cm^3 Ge (Li) detector with nuclide 2 cm distance.
[c] Elements are listed in a given group in decreasing order of sensitivity.

where FNAA is probably the most sensitive technique available.

ENAA is a useful extension of INAA in that it enhances the activation of a number of trace elements relative to the major matrix elements. Here, epithermal is taken to be neutrons with energies from the Cd cut-off of 0.55 eV up to approximately 1 MeV. In general, the activation cross-sections of the matrix elements of environmental samples are inversely proportional to the neutron energy (1/v law). The trace elements also follow this general trend but many of them have large activation cross-sections at specific energies in the epithermal energy region. Thus, in irradiations with mainly epithermal neutrons the relevant trace elements are well activated and the resultant γ-ray peaks are usually more distinct and so more precisely analyzed than when using thermal NAA, even though the peaks may actually contain less counts. ENAA is particularly useful for biological and seawater samples which contain high concentrations of Na and Cl, which follow the 1/v law.

Finally, a number of more specialized techniques can be used to enhance the sensitivity of INAA. One of these is cyclic instrumental neutron activation analysis (CINAA), which is used to improve the measurement of some very short-lived isotopes (e.g. Pb, which can be activated to ^{207m}Pb with 0.8 s half life) by repeated irradiation and counting. CINAA has also been used to improve the determination of Cu, F, Pb and Se amongst others, in biological samples.

A special form of INAA results from the γ-rays emitted immediately following the capture reaction. These are known as prompt gamma rays and, hence, the method is called prompt gamma neutron activation analysis (PGNAA). Here, irradiation and counting have to be undertaken simultaneously but in principle, all elements are determinable by PGNAA since all elements capture neutrons but detection limits (DLs) vary from ~0.1 ppm up to tens of ppm depending on the element and the available neutron flux. Chau et al.[16] have discussed the wider application of PGNAA to environmental and biological materials.

3 ANALYSIS OF BIOLOGICAL MATERIALS

3.1 Introduction

The determination of the minor and trace elements in biological materials can have a number of objectives. One

of these is to estimate the normal or baseline concentrations of elements so that any significant deviations from these levels can perhaps be related to specific changes or diseases in the organism or tissue. A second objective is to determine those elements deemed essential or toxic to an organism and at what levels they function in these roles. Thus, in humans some 18 elements (Ca, Cl, Co, Cr, Cu, F, Fe, I, K, Mg, Mn, Mo, Na, Ni, P, S, Se and Zn) are now thought to be essential for the correct metabolism of an individual, ranging from a daily requirement of 2–5 g for K down to 3 μg for Co. It is well known, however, that almost any substance taken in excess will ultimately become harmful, i.e. toxic. In other words, there is no essential qualitative difference between essential and toxic elements. A third objective of trace element determinations is to ascertain if the concentration of an element(s) in a particular tissue or component can be an indicator of a specific disease. An example is the elevated concentration of Cu in the livers of people suffering from Wilson's disease.

3.2 Sampling

In environmental monitoring the quality of the data is related to three principal factors: (1) the design and performance of a representative sampling program, (2) the satisfactory storage of the sample to prevent changes to the analyte and (3) the use of suitable analytical methods which yield the requisite accuracy and precision.

Sampling is a problem for all types of material but sampling of biological materials is particularly difficult. This is in part due to the very complexity of the components of biological samples but also in part to the often limited amounts available and to potential changes to the constituents following sampling, e.g. coagulation of milk and blood or general bacterial attack. Thus, sampling may be the key factor in the quality of the data for some biological analyses.

3.2.1 Methods of Sampling and Sample Preparation

An important consideration in the collection of vegetation for any type of analysis is that the sample variation within a collection area probably greatly exceeds all other analytical variations. This necessitates careful consideration being given to the collection strategy and will often require proper statistical design for sample collection if meaningful results are to be obtained. Such considerations are beyond the scope of this article but are treated by, for example, Barnett[17] and Webster.[18] Vegetation in this context could include grasses, vegetables of all sorts, leaves of trees or needles from conifers and fresh water and marine plants, particularly seaweed.

Sampling tissues, organs, and so on is a specialized job and normally the analyst will be supplied with the necessary material from a suitable laboratory. Urine and faecal samples may be required from both humans and animals, and suitable arrangements for their collection are required.

3.3 Standard Reference Materials

In order to verify the quality of the data from INAA, the availability of SRMs with certifiable (trace) element concentrations is important. They may also be used as standards in some circumstances in the comparator method. Some 200 SRMs are now currently available, covering virtually all the matrices met within the analysis of biological materials. The International Atomic Energy Agency (IAEA) in Vienna has issued a comprehensive list of these SRMs and their suppliers.[19] Such materials conform to the basic requirements of certifiable element concentrations, homogeneity and long-term stability. Byrne[20] has given a useful survey of the role of SRMs in environmental monitoring.

3.4 Irradiations

Biological samples are normally irradiated in acid-cleaned polythene vials for irradiations up to a day or so. For much longer irradiations, quartz ampoules are normally used. These must be cleaned in boiling aqua regia followed by thorough rinsing in doubly distilled water prior to irradiation. A blank irradiation, with no sample present is usually necessary owing to the presence of trace impurities such as K, Na, Sb and Sc in the silica. A suitable standard(s) is used in the comparator method, although Byrne and Dermelj[21] have described a method based on the use of an endogenous internal standard of already known concentration for the analysis of biological samples which eliminates the need to know the sample mass and greatly reduces errors due to geometrical differences, and in RNAA it eliminates the necessity of determining chemical yields.

Owing to the generally low concentrations of nonmatrix elements in biological samples coupled with the fact that the matrix elements (C, H, N, O and P) do not produce γ-emitting nuclides, biological samples are often irradiated for long periods to enhance the activities of the analytes. The problem of bremsstrahlung from some of the induced β-emitters (e.g. ^{32}P) is reduced by placing a plastic absorber between the samples and the detector. Using a flux of approximately $10^{17}\,nm^{-2}\,s^{-1}$ the sensitivity for many elements is inferior to that of many other analytical procedures and is frequently slower. Even if fluxes greater than $10^{17}\,nm^{-2}\,s^{-1}$ were available, they could rarely be used for biological samples owing to the radiation damage that they would cause.

In INAA of biological materials, the normal procedure is to use a short irradiation of about 30 min to determine short-lived nuclides such as ^{27}Al, ^{27}Mg, ^{47}Ca, ^{52}V, ^{56}Mn, ^{80}Br, ^{86m}Rb, ^{101}Mo and ^{128}I, together with ^{24}Na, ^{42}K and ^{82}Br. Very short-lived isotopes such as ^{38m}Cl(710 ms), ^{79m}Br(4.8 s), ^{20}F(11.1 s) and ^{77m}Se(18 s) can also be determined using a pneumatic transfer system in the technique of short-time NAA. Here, CINAA may be effectively used to increase the sensitivity of the determination. Short-time NAA allows the determination of some elements, e.g. Pb and Se, that would otherwise require a postirradiation chemical separation. These short irradiations are then followed by a long irradiation of 8–48 h duration for the determination of ^{51}Cr, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{76}As, ^{86}Rb, ^{121}Sb, ^{137}Cs, ^{133}Ba, lanthanides, ^{182}Ta, ^{233}Th and ^{233}Pa(U). INAA is very useful for samples that are difficult to obtain, such as biopsy samples. Because of the essentially nondestructive nature of the technique, the samples are available for repeated determinations or analyses by other methods.

The high activities of ^{24}Na, ^{38}Cl, ^{56}Mn and ^{82}Br induced in most biological samples mean that many trace elements can only be determined after pre- or postirradiation chemical separation to remove these interfering nuclides or alternatively, by employing ENAA since the interfering nuclides follow the 1/v law. ENAA is particularly useful for the determination of Ag, As, Br, Cd, Cs, I, Mo, Rb, Sb, Se, Sr and Zn. Silicon can be determined by ENAA in biological materials but the corrections for the interfering ^{31}P(n,α)^{28}Al and ^{27}Al(n,γ)^{28}Al reactions are so large for fruit, legumes, meat and milk as to make the method inapplicable. Both Cd and B compounds have been used as thermal neutron absorbers, although there can be thermal problems when using boron compounds (BN and B_4C_3). FNAA is also used as a complement to INAA and ENAA to extend the range of elements determined in biological materials, e.g. N, P, Si and Ca. It has been used particularly for the determination of nitrogen which, in turn, has been used as an estimate of the protein content of samples. The reaction used is ^{14}N(n,2n)^{13}N, giving a positron-emitting nuclide with a half-life of 9.97 min.

Some elements in biological samples are also determined by PGNAA. It is particularly useful for boron determinations using the 478-keV γ-ray from ^{11}B. The nondestructive nature of the method makes it useful for studying the uptake of boron by plants from the soil.[22]

3.5 Radiochemical Separations

Although for reasons discussed in section 1, instrumental forms of NAA are usually preferred because of the simplicity and ability to process large numbers of samples in a relatively short time and to retain the sample intact, nevertheless, for certain applications there is no escaping dissolution of the sample and chemical processing. Generally, postirradiation separations are favored because of the lack of contamination problems but occasionally preirradiation separations must be used. In either case, the procedures for the dissolution of materials may result in the loss of more volatile trace elements such as Hg, I, Sb, Se, and when dry ashing is used, even elements such as Ce, Co, Mn, Pa, Ru and Zn can be partly volatilized, even at low ashing temperatures.

3.5.1 Preirradiation Separations

These are usually performed when there is the possibility of rapid sample deterioration or in order to reduce the amount of activity to be handled after the irradiation. In either case, either the analyte is separated or the matrix elements removed. When using preirradiation separations, because there is the possibility of chemical contamination, a blank determination is necessary. The removal of sodium prior to irradiation may be required owing to its short half-life (15 h) and the intense activity that may be induced in some samples. This can be achieved by dissolving the sample, stirring in powdered hydrated antimony pentoxide (HAP) and then filtering to remove the HAP which will contain most of the sodium.

3.5.2 Postirradiation Separations

In order to improve the sensitivity of the determination of a number of elements by removal of spectral interferences, or to enable a general reduction in the background activity and elimination of any blank value, a postirradiation separation is used. An important aspect of modern RNAA is the development of standardized and automated separation systems which can handle relatively large numbers of samples and are less prone to radiation hazards, although these tend to be laboratory specific. It has been found to be more effective to have a number of separate separation procedures for a number of small sets of elements rather than a single complicated procedure for all the elements, usually at the expense of high and constant yield.[23]

The majority of postirradiation separations use either ion-exchange chromatography or solvent extraction but precipitation is also used. Here the addition of carriers is essential for all the analyte elements as well as major interfering elements. Platinum has been determined by electrodeposition from acid solution using a cell with a niobium cathode. A DL of about 1 ppb has been achieved with this technique.

A more recent development has been the introduction of new ion-exchange materials, particularly inorganic exchangers. An interesting example is analysis for Li which can be determined in biological materials by

using the following reactions: $^{6}Li(n,\alpha)T$, $^{16}O(t,n)^{18}F$. The sample solution is placed on a ZrO_2 column and the ^{18}F absorbed. Interfering nuclides are eluted off with pH 1 to ~3 solution and the column then counted to determine the ^{18}F activity.[24] These developments have been reviewed by Braun et al.[25]

One of the more rapid methods for the separation of trace elements following dissolution of the sample is by adsorption on activated carbon (AC).[26] The solution is simply filtered through a layer of AC on a membrane filter. The number and type of elements that are collected in a single filtration can be varied by the addition of certain reagents to the solution. Thus, filtration at low pH without the addition of any reagents will result in the adsorption of ^{64}Cu, ^{110m}Ag, ^{197}Hg, ^{198}Au and $^{233}Pa(Th)$. If the filtrate from this is then treated with ammonium pyrrolidine dithiocarbamate (APDC) and oxine and filtered again through fresh carbon, this results in the adsorption of ^{64}Cu, ^{99}Mo, ^{122}Sb, ^{187}W and ^{197}Hg. This can be extended to the point where some 15–25 radionuclides can be collected on different carbon fractions which can then be counted to determine the relevant nuclides.

3.6 Applications

3.6.1 Tissues, Blood and Bone

Almost all human organs and tissues have been subjected to analysis by INAA. Many of these studies have simply determined the levels of all the detectable elements. Others have been used to assess levels connected with specific diseases. Some international comparison studies have revealed the difficulties in obtaining reliable data for some elements in some tissues. Values for As, Cd, Hg and Pb obtained by a number of analytical techniques including NAA in bone, lung and brain samples are rather poor.

A number of studies have focused on the analysis of the brain by INAA with attempts in particular to try to relate instances of decreased concentrations of specific elements with Alzheimer's disease.[27] It is well known that high concentrations of Al in the brain are associated with the disease but other trace elements may play a role.

Blood has been widely analyzed by INAA, again with much of the emphasis on the concentration range of trace elements found in blood or blood components.[28] Some efforts have been made to correlate various diseases with blood composition and there is evidence for some specific changes of blood composition for some occupational groups. Also, certain elements (e.g. La and Tb) tend to increase in concentration with age.

Much of the work on bone has been directed primarily at determining the fluoride content of the bone, due to the potential role of fluoride in the development of bone diseases. This has also led to investigations of changes of other elements in bone such as Al, Ca, Mg, Na and P from various diseases or forms of treatment. Al, Mg and Na are all best determined by INAA but FNAA is the more sensitive method for Ca, F and P. If lower energy neutrons (<10 MeV) are used, the most sensitive $^{19}F(n,\alpha)^{16}N$ reaction is effectively employed.[29] An interesting application of bone analysis is the correlation of the N/F ratio in fossil bones with the age of the bone, F increasing with age as it replaces the P in apatite.[30]

3.6.2 Biomonitoring

An increasing trend in environmental analysis is that of biomonitoring. Here, some living system (usually a plant) which incorporates and concentrates a particular pollutant is sampled and used to estimate the total amount of the pollutant over a wide area or to estimate the effect of pollutants on the local ecosystem. In this way the biomonitor records environmental changes and can be used to follow the effect of changed pollutant conditions. Alternatively, from determining the concentration of a particular pollutant in specific tissues or body fluids in human beings, biomonitoring can be used to estimate better the total dose absorbed and to assess the risk of environmental or occupational exposure to the pollutant.

Since the late 1960s there have been numerous studies of the trace element composition of human hair (and to a lesser extent, nails) with the aim of estimating patterns of composition for normal populations in a given region or geographical area and then using these ''normal'' patterns to reveal significant variations which may indicate exposure to high levels of a pollutant or possible correlations with certain diseases. The IAEA has coordinated international programs of nuclear-based research on hair analysis.[31,32] The later IAEA program[32] was directed towards collection of hair only from males of a certain age who died by accident or were subject to sudden unexpected death.

The data from the first IAEA program provided data on 40 elements. It showed that use of geometric means and standard geometric deviations gave a much better characterization of the distribution of trace elements in most cases than the equivalent arithmetic ones. Also, statistical variations of element concentrations could be quite large without being ''abnormal''. Studies have also revealed geographical differences in some elements, e.g. Se higher in Asian than European populations.

More frequently, however, the interest is in how the concentration of elements in hair reflects internal contamination or burden of an element(s). An example is that of peasants who consumed grain contaminated with a mercury fungicide.[31] Many of these ingested toxic

quantities and variations along the length of hair recorded the history of the poisoning.

3.6.3 Plants

The analysis of trace elements in plants has proved a fruitful field for both RNAA and INAA. Again, much of the work has concentrated on determining the range of trace elements found both in whole plants and in different plant structures such as seeds. Essentially the same 15–20 elements found in biological materials are also determined in plants by INAA.[33] RNAA then yields a further 10–12 elements, among them Ag, Au, Cd, Cu, Hg, Mo, Sr and Zn. FNAA and ENAA also extend the range of elements determined, including nitrogen which is useful for determining the protein content of plants.

4 ANALYSIS OF WATER

4.1 Introduction

The analysis of water for trace elements and, in particular, trace metals is one of the most important aspects of environmental monitoring. This results from the role of water in all aspects of life on our planet, ranging from the purity of drinking water to the pollution levels in the seas and oceans. At the same time the seas provide a valuable source of some heavy precious metals. In addition, the data obtained can be used to elucidate transport processes in the aquatic environment.

Water can be broadly segregated into sea, surface (lakes, rivers, drinking, etc.), ground and waste. Apart from the latter, levels of most elements in water are at the trace or ultratrace level (see Table 2). The exceptions to this general rule are the concentrations of Na, Cl and Br and one or two other elements, particularly in seawater. Levels of certain elements in wastewater can also be high but vary according to the source of this water.

In one respect, water presents the perfect matrix for determinations of trace elements by NAA since it is essentially not activated. On the other hand, the low concentrations of most elements would require the use of large sample volumes and long irradiations with high neutron fluxes for measurements by INAA. These requirements present several problems: first, there is a

Table 2 Concentration of elements in seawater and fresh surface waters determinable by INAA

Element	Seawater[a] concentration (ppm)	Fresh surface waters[b] mean concentration (range) (ppm)	Element	Seawater concentration (ppm)	Fresh surface waters mean concentration (range) (ppm)
Cl	1.95×10^4	7.8(4.9–12.1)	U	3.2×10^{-3}	$\sim 1.0 \times 10^{-3}$

[a] Data from *Seawater: Its Composition, Properties and Behaviour*, Open University Course Team, Pergamon Press, Oxford, 1989.[34]
[b] Data from D.A. Livingstone, 'Chemical Composition of Rivers and Lakes', *Data of Geochemistry*, 6th edition, US Geol. Survey Prof. Paper 440-G, Chapter G, G1–G61, 1963.[35]

severe limitation on sample size in most reactors and second, long or intense neutron irradiation of water results in the radiolysis of the water leading to problems from the subsequent gas generation. Shorter irradiation times result in unacceptably long counting times. A final factor militating against INAA of many water samples is the high activities of ^{24}Na, ^{38}Cl and ^{82}Br induced in these elements. Although these are all relatively short-lived activities, it makes handling the sample following irradiation difficult and precludes the determination of the short-lived trace elements in many cases.

Consequently, water as such is rarely irradiated (although methods have been developed to allow irradiation of large volumes of water, up to 250 cm^3 for 20 h) and the more usual approach is to concentrate the elements prior to irradiation in a solid form (preconcentration) or, more rarely, following the irradiation (postconcentration).

4.2 Sampling

Environmental sampling of liquids will usually involve liquids flowing in open systems (rivers, canals, effluent streams, etc.) or liquids in large open bodies (seas, lakes, ponds, etc.). The major difficulty in sampling flowing liquids for this type of system is that it may vary in two dimensions, i.e. both with depth and along its length. The sampling will probably have to take into account changes in flow rate, both seasonal and on a shorter timescale.

Samples are collected in wide-mouth bottles or small buckets, probably of plastic construction. If samples are required at various depths then special containers are used which can be filled at a specific depth and then closed before removal to the surface.

For water in large open bodies it will again probably be necessary to obtain samples from various parts of the body and at various depths. The samples can be taken with similar devices discussed above. Special devices have also been constructed for sampling relatively shallow lakes and ponds on a regular basis to obtain samples quickly from several fixed depths.

4.3 Preconcentration Procedures

4.3.1 Evaporation and Freeze Drying

These are both simple methods, can handle large volumes of water and are free of potential chemical contamination. They do, however, suffer from the time required for their completion and the fact that no reduction in the Br, Cl or Na content occurs. Freeze drying is preferred as even evaporation at relatively low temperatures can result in the loss of some volatile elements and possible contamination of the open system. The resultant solid that is produced can then be subject to INAA with the above limitations due to the presence of Br, Cl and Na.

4.3.2 Chemical Preconcentration

The aim here is to concentrate the trace analytes whilst separating them from potential interfering elements at the same time. In general, the most useful methods are those that concentrate a large number of trace elements, although procedures have been developed for the concentration of a small number of elements that are of particular concern or troublesome to determine by alternative concentration techniques. The most appropriate method will be one which is rapid and can actually be carried out at the sampling site, thus eliminating problems due to adsorption or desorption during storage of the sample. Examples of such methods are filtration, adsorption of the analyte during passage of the water through a column of a suitable solid, solvent extraction or the collection of a precipitate. Direct precipitation is usually not possible owing to the very low levels of most of the elements. The answer is to use coprecipitation whereby a suitable bulk chemical is precipitated and this carries the trace elements. In particular, organic coprecipitants are suitable as C, H, O and N do not form radioisotopes except for small amounts of very short-lived ^{16}N and ^{19}O. Alternatively, the trace elements may be scavenged from solution by a suitable solid, e.g. MgO and AC. A method requiring more time and involving greater complexity is ion exchange, mainly of complexed species. Rarely, electrodeposition is used for some specific elements (e.g. Hg). The enrichment factors for these techniques, however, are usually much smaller than those obtained by coprecipitation methods.

The major drawback of preconcentration is the potential contamination of the final product by the chemicals used. Hence, the emphasis is on the purity of all the chemicals used in a procedure. A second disadvantage is the necessity to determine a blank value for the elements determined, in other words, carry out the entire procedure with very pure water to determine the contamination from the procedure itself. Finally, the chemical yield for the analytes must be determined or it must be established that a given procedure produces an essentially quantitative yield. Despite these drawbacks preconcentration methods are the most widely used in the analysis of water samples by NAA.

4.3.2.1 Coprecipitation Coprecipitation may be conveniently divided into methods based on either organic or inorganic precipitants. Some more recent organic precipitants have also incorporated metals that produce only very short-lived or long-lived γ-emitting nuclides or only β-emitters to increase yields, e.g. Pb and Bi in conjunction with the precipitant pyrrolidine dithiocarbamate (PDC).

Organic Precipitates. A number of organic compounds, mainly chelates, have been used in preconcentration by coprecipitation. Thus, oxine (8-hydroxyquinoline) is used for the determination of Cd, Cu and Mn in seawater and, in the form of reversed-phase extraction, chromatography using silica-immobilized oxine has been developed for the simultaneous determination of Co, Cd, Cu, Hg, V and Zn in rain and surface waters.[36]

Dithiocarbamates, in the form of the Pb or Bi salts of PDC carry many elements when coprecipitated with them, which is carried out at pH < 6 for the best yields for most elements. APDC in the presence of Bi^{3+} carrier carries Cd, Co, Cu, Mo, V and Zn quantitatively from lake and river-water samples[37] and arsenic as As(III) has been determined in surface waters by precipitation of the dibenzyldithiocarbamate complex followed by filtration and then INAA of the solid. Dithiocarbamic acids possess an S−H group which is readily oxidized in aqueous solution to insoluble disulfides which form the precipitate. Some other organic molecules with oxidizable S−H groups have been examined as potential coprecipitants,[38] in particular quinolyl-8-thiol and its derivatives which give rise to bis(8-quinolyl) disulfides. Waters with high fulvic or humic acid concentrations result in poor or no coprecipitation of trace metals and so these organic contaminants in the water have to be destroyed prior to disulfide coprecipitation.

PAN (1-(2-Pyridylazo-2-naphthol)) when added as a dilute solution in ethanol to the water sample results in the PAN crystallizing out, whereupon the solid is filtered and collected for irradiation. In this way, excellent recoveries of Cr(III), Cu, the lanthanides, Mn(II), Ni and Zn can be obtained together with lower recoveries of Ag, Cd, Co, Fe, Hf, Hg, In, Sc, Sn, Th and U in surface and seawater.[39] Under these conditions, preconcentration factors $> 2 \times 10^5$ are possible. Combinations of these precipitants with each other or other organic complexes are also used to improve the yield or separation of various elements. Examples are bismuth salts of mixed oxine and thionalide (2-mercapto-*N*-2-naphthylacetamide) used in combination with Pb or Bi salts of (PDC) for the determination of As, Cd, Co, Cr, Cu, Fe, In, La, Mn, Mo, Ni, Sb, Sc, Se, U and Zn in tap water and seawater. A mixture consisting of APDC, Cupferron and 1-(2-thiazolylazo)-2-naphthol (TAN) can be precipitated from drinking water and seawater samples at pH 6 for the determination of Cd, Co, Cu, Hg, Mn, Th, U, V and Zn.[40] Finally, oxine is also used to determine Al, Cu, Mo, V, U and Zn in underground, lake and seawater by converting these metals to oxine chelates, extracting these with molten *o*-phenylphenol and irradiating the subsequently cooled solid.

Inorganic Precipitates. A problem with some potential precipitates is that the matrix metal, e.g. Fe, is activated requiring its removal either prior to irradiation or prior to counting. $Fe(OH)_3$ has been used to collect a number of trace inorganics from water. Arsenic in seawater can be determined by coprecipitation with $Fe(OH)_3$, with the precipitate redissolved in acid and the solution irradiated.[41] The As (^{76}As) is isolated on a column of Al_2O_3 for counting. The same precipitant can be used for the determination of several lanthanides in river and seawater following a group separation after irradiation. A combination of $Fe(OH)_3$, $Al(OH)_3$ and PbS has been used to determine a number of elements in river water, each coprecipitant removing a specific set of elements.[42] PbS coprecipitates Ag, Al, Ba, Br, Cl, Cu, I, In, K, La, Mg, Mn, Na, Sb, Sn, Sr, U, V and Zn from various potable mineral waters. Lead phosphate has also been used to coprecipitate Ag, Cd, Cr(III), Cu, Mn(II), Th(IV), U(VI) and Zr(IV) from surface and seawater.[43] Bismuth sulfide, Bi_2S_3, has been used to coprecipitate a limited number of elements, e.g. Pd in seawater. Short irradiations produce no activity from Pb or Bi and the beta activity from the sulfur and phosphorus is not a problem.

4.3.2.2 Scavenging This term as used here refers to the process whereby a finely divided solid such as carbon or MgO is added to the water sample with the aim of adsorbing trace elements present. The process may, in fact, involve physicochemical processes other than adsorption, such as ion exchange. In general, scavenging satisfies the requirements of a fast simple means of preconcentration.

By far the most widely used method of scavenging is that based on AC.[26] In its simplest form, this simply requires the water sample to be stirred with a suitable mass of AC (or for the water to be poured through a column of AC), followed by filtration to collect the AC and then irradiation of the dried solid. Ultrapure carbon results in virtually no activity since the carbon itself is not activated and only trace impurities produce γ-emitters. The levels of these trace impurities vary according to the source of the carbon and this requires a blank measurement, so that the sample data can be corrected where necessary. Preparation and irradiation of a blank are necessary for all scavenging techniques.

In practice, it is found that adsorption isotherms for almost all elements are increased by chelation of the element so that the element is adsorbed as the chelated species.[26] Commonly used chelates are APDC (Cd, Co, Cr, Cu, Mn, Mo, V and W) and L-ascorbic acid (Se, U). Bismuthiol-II (3-phenyl-5-mercapto-1,3,4-thiadiazole-2(3*H*)-thion potassium salt) has also been used to chelate Se. For Hg no chelation is used but the

process involves reduction of Hg with stannous chloride ($SnCl_2$) followed by its volatilization and subsequent collection on AC.

Magnesium oxide, MgO, was originally applied to the determination of trace elements in surface water.[44] In this process light MgO is stirred with the water for 30 min and then allowed to stand for ~8 h. This produces a stable mixture of MgO and $Mg(OH)_2$ of pH 10, which then adsorbs trace elements from the water via an ion-exchange mechanism. The filtered and dried solid can be subject to INAA since, again, Mg does not produce any long-lived activity. In this way, Ag, As, Au, Cd, Ce, Co, Cr, Fe, La, Mo, Ni, Sb, Sn, U and Zn are all absorbed. Washing the irradiated MgO with water removes interfering ^{24}Na, ^{42}K and ^{82}Br. It is also found that the lower oxidation states of some elements are much better absorbed than the higher ones [Cr(III) > Cr(VI), Sb(III) > Sb(V), Se(IV) > Se(VI)]. This provides for the possibility of separating the oxidation states of these three elements. When MgO scavenging is used for seawater, adsorption from acidified seawater is necessary in order to destroy the chloro complexes of some metals such as Hg and Ni and allow their absorption as the cationic species.

4.3.2.3 Ion Exchange The method is used not only as a preconcentration technique, but also as a means of removing many interfering elements from natural waters. A great advantage of ion exchange over other preconcentration techniques is that virtually unlimited volumes of (nonsaline) water can be used in the exchange of trace elements. After washing the column, the resin can be removed, dried and subjected to INAA. For conventional acidic cationic or basic anionic exchangers, seawater is obviously a particular problem owing to the presence of large amounts of Br, Cl and Na in particular and they are not normally used. In general, anionic exchangers are more widely used than cationic ones for the preconcentration of trace metals from surface waters, and metals determined in this way are Ag, As, Au, Cd, Co, Cu, Hg, Mn, Th, V and Zn.

In the case of seawater, the choice is usually between a chelating resin or an inorganic exchanger. Chelating resins readily take up those metals that form strong chelates with the functional group. This excludes Na to a great extent so that large volumes of seawater can be used. Such resins take up Al, Ba, Ca, Cr, Eu, Fe, La, Mn, Mo, Ni, Sc, Sn, Ti and V in addition to those mentioned with anion exchangers. Thus, carboxymethylated polyethyleniminepolymethylenephenylene isocyanate chelating resin can be used for the preconcentration of Cd, Pb and Zn from seawater or Cd, Co, Cu, Hg and Zn from surface water by shaking the water with the resin beads. Enrichment factors of ~400 are obtained with this material.[45] Conventional polystyrene powder containing conformationally flexible aminocarboxylic acid groups have high sorption for most elements at pH 3–7 except the alkali metals. Direct INAA on the sorbent allows determination of Au, Ba, Cd, Co, Cr, Cu, Eu, Fe, Hg, In, La, Mn, Sc, Sr and V.

The most commonly used inorganic exchanger is HAP. The material is prepared, crushed and sieved and then packed into a column as with an exchange resin. The key feature of HAP is its ability to absorb Na strongly. Thus by passing seawater through such a column, the interfering Na is removed. Other chemically modified exchangers have been used for preconcentration in special circumstances.

4.3.2.4 Solvent Extraction This method like coprecipitation or scavenging has the advantage of rapidity and simplicity. Usually, the trace metals are extracted as chelates and the method simply requires the water sample to be shaken with the chelate in an immiscible organic solvent (usually CCl_4 or $CHCl_3$). The metal reacts with the chelate and the metal chelate is then extracted into the organic phase. APDC and sodium diethyldithiocarbamate (NaDDC) are the most widely used chelating agents. Extractions based on both these agents are pH-dependent so that the elements extracted can be controlled by controlling the pH of the water sample. Following the extraction, the organic solution may be subjected to INAA or sometimes a back extraction is performed so that the extracted metals are back extracted into an aqueous phase for irradiation.

4.4 Postirradiation Procedures: Radiochemical Neutron Activation Analysis

It was argued at the beginning of this article that a major advantage of NAA over other analytical techniques was the possibility of chemical separation following irradiation (RNAA) by which contamination problems were eliminated. Unfortunately, with water samples, RNAA is not so advantageous. This is partly due to the limited volume of water and neutron dose that can be used in the irradiation, usually resulting in poor DLs even after chemical separation unless inordinately long counting times are used. Additionally, the presence of Br, Cl and Na, particularly for seawater samples, makes sample handling immediately after irradiation very difficult and also creates problems for the determination of short-lived elements. Thus RNAA is much less used for water analysis than for solid environmental samples.

The majority of postirradiation separations are based on either ion exchange or solvent extraction. A method that is commonly used is to pass the irradiated water through a column of HAP to remove (mainly) ^{24}Na, which is often the most active nuclide present a few hours

after irradiation. This one-step procedure may then allow many of the other elements to be determined directly. Other inorganic exchangers have been investigated for selective removal of specific nuclides, with variable success. Conventional anion exchange resins are the most commonly used exchangers where chromatographic or group separations are required. For solvent extraction, extraction of chelates (PDC, in particular) is used with extraction into a number of solvents (CCl_4, $CHCl_3$, methyl isobutyl ketone (MIBK)).

Coprecipitation is occasionally used, as in the determination of As, Mo, Sb and Se, coprecipitated with Bi_2S_3. Substoichiometric isotope dilution analysis has also occasionally been used (determination of Cr). Finally, iodine is sometimes determined in irradiated water by isotope exchange.[46] Here, irradiated water is shaken with a solution of iodine in CCl_4 when some 95% of the active iodine present in the water can be exchanged and then determined by counting an aliquot of CCl_4.

4.5 Biomonitoring and Hydrological Studies Using Neutron Activation Analysis

Monitoring the marine environment is one of the most difficult but most essential tasks in environmental studies. One method of monitoring is to analyze plant or animal tissues which are known to incorporate or concentrate pollutant elements. These materials are more amenable to INAA than the water itself but reflect the marine conditions. An example of this is the brown algae which inhabit most of the world's coastal seas and show an affinity for a number of pollutants, such as Ag, As and Sr, and levels of many other trace elements, reflecting the waters they inhabit. They have been shown to be useful as monitors of trace elements in coastal waters.

Other marine plants are also useful in this context such as certain phanerogams.[47] Some 43 trace elements have been determined in this plant by INAA, and comparisons between those growing in polluted and unpolluted areas reveal that the plant can be used to assess levels of pollution provided sampling is careful. In addition, these plants concentrate elements known for their biotoxicity from seawater and so can be used as indicators of this type of pollution.

The levels of As in drinking water have also been assessed by analysis of toenail clippings using NAA.[48] It was found that a 10-fold increase in the concentration of As in the water led to about a twofold increase in toenail As. Thus, toenail As levels could be used to assess As levels in water of a particular region.

NAA has begun to play a part in hydrological studies in recent years. In the past, radioactive tracers were introduced into aqueous systems to study the behavior of large bodies of water, necessitating the use of large quantities of long-lived nuclides. Fears over potential contamination of the environment have led to the use of activable tracers instead. Here, an ordinary stable element but one not present in the water, is introduced. At a later time, the water is sampled, treated in a manner previously discussed and then activated. Measurements of induced activity indicate dispersal and other properties of the element and, hence, information on the water system itself.[49]

5 ANALYSIS OF AIR PARTICULATES

5.1 Introduction

The analysis of the air constitutes the second major area of environmental analysis, along with that of water. The importance of air arises from its fundamental role in the existence of all living things. The air we breathe is essentially a mixture of gases with suspended solid particles and liquid droplets which are referred to as aerosols. NAA of air is essentially confined to the analysis of the suspended particulate matter. Although this may seem a very restricted role for NAA, the position of particulate matter in human health is currently regarded as one of the most serious environmental problems. There is particular concern regarding particles with aerodynamic diameters less than 10 μm, the so-called PM10. The IAEA began a global coordinated research program (CRP) in this area in 1992 and a report of the work has been issued.[50] A review of this whole area and methods of determining compliance with current United States air quality standards for suspended particles has also appeared.[51] An earlier review of the role of activation techniques in the analysis of aerosols also emphasized the importance of these particles.[8]

5.2 Particulate Matter: Sources, Composition and Inhalation

The particulate matter found in air covers a wide range of sizes from about 100 μm down to about 0.01 μm diameter; however, the most important size range with respect to human health is that fraction $< 10\,\mu m$ diameter. This range is further subdivided into those particles between 0.08 μm and $\sim 2\,\mu m$, which constitute the fine particle size fraction and those between $\sim 2\,\mu m$ and 10 μm which constitute the coarse particle size fraction. The majority of fine particles are of anthropogenic origin whereas the majority of coarse particles are of geological origin. Many schemes for sampling the air allow separation of these two fractions. The main sources of PM10 are shown in Table 3. The actual fraction of each of these components present in PM10 at a given site will be

Table 3 Relative abundance of elements, inorganic chemicals and carbon in PM10s from different emission sources

Source of emission	Dominant particle size	Relative abundances of elements, inorganic chemicals and carbon in percent mass			
		<0.1%	0.1–1%	1–10%	>10%
Paved road dust	Coarse (2.5–10 μm)	Cr, Sr, Pb, Zr	SO_4^{2-}, Na^+, K^+, P, S, Cl, Mn, Zn, Ba, Ti	(EC), Al, K, Ca, Fe	OC, Si

strongly dependent on the source and it is possible to classify and identify sources of PM10 from the relative values of these fractions.

The reason for the interest in PM10 is that these represent the inhalable fraction of particulates since most particles larger than 10 μm are removed in the mouth or nose and so do not enter further into the body. Up to 60% of particles < 10 μm diameter may be deposited in the lungs. The health implications lie in the fact that these particles are contaminated by a wide range of elements and compounds, including toxic and carcinogenic ones. In addition, Si particles may result in lung damage even at low levels.

5.3 Sampling

The majority of environmental air sampling involves aerosol collection and the most widely used methods of collection are by filtration and impingement. Filtration is simple and provides sufficient material for subsequent NAA. A basic filtration unit consists of a filter holder, filter, an air mover (pump) and a flow-rate meter. Uniform flow of air across the filter is desirable since measurements of element concentrations are nearly always made directly on the filter. Accurate measurement of flow rate is also important in order to determine the total volume of air from which the sample was collected.

A wide variety of filter media are available but the two types most routinely used for environmental sampling are fibrous filters (cellulose paper or glass fiber mainly) and membrane filters (gel-type or nuclepore). Cellulose papers are relatively cheap and robust but suffer from variability in collection efficiency. Nevertheless, for the rapid collection of sufficient material for an analysis they are quite adequate. Glass fiber filters have more uniform collection efficiencies and tend to collect more material at the surface of the filter but may give rise to high blank values for some elements.

Membrane filters are quite different in construction from fibrous filters but the most significant difference to the fibrous type is that the pore size is both controllable and variable and they can be used for the collection of particles down to 0.1 μm. Their collection efficiency is better than for fibrous filters and for a pore size of 0.6 μm they collect essentially all particles. For the collection of relatively large amounts of material (several mg), however, the fibrous type is the usual choice.

Impingement for the collection of aerosols relies on a stream of air being forced through a nozzle at the back of

which is some form of obstruction. Particles carried in the airstream then collide forcibly with the obstruction and tend to collect on it. The collection efficiency is usually increased by attaching a ''sticky'' film to the surface of the obstruction such as a film coated with petroleum jelly. The main use of impingers is the ability to collect fractions of different particle size so that the range of particle sizes associated with the majority of the airborne elements can be determined. The major disadvantage of impingement devices, however, is the relatively small mass of material that can be collected. The cascading impactor is perhaps the most useful design of impingement equipment. It consists of a series of stages, each of which collects successively smaller particle fractions.

Kist et al.[52] have described a sampling system for the small-size particles (<0.1 μm) and vapor-gas phases involving the use of very thin polyethylene films placed directly in the atmosphere. Various configurations were investigated and data indicated the potential for trapping submicron and vapor-gas aerosol phases.

5.4 Measurements

In the case of particulate matter collected alone, e.g. from an impaction collector, the material can be packed directly into cleaned polyethylene irradiation vials or compressed into a pellet first. For filters, the filters plus deposit may be folded and then packed into the irradiation vials. Even better is to compress the filter into a pellet which gives improved geometry for both irradiation and counting. Some filters are brittle and may crumble whilst being handled with possible loss of some of the deposit. Flexibility can sometimes be improved by exposure to acetone. For long irradiations, aluminum or silica may replace polyethylene which may become brittle after exposure to a high neutron fluence. Standards are usually prepared by pipetting accurate volumes of solution containing known concentrations of the elements under investigation onto filter discs and then after drying, treating them the same as the samples. A blank correction is always required when any type of filter disc is used since these always contain measurable levels of some trace elements, requiring a correction to the analyzed sample data. For the usual comparator method of INAA, suitable standards are required (either a single multielement standard, frequently a suitable SRM, or a series of filter standards containing only a single element).

Most of the trace elements in air particulate samples can be determined by INAA. This is particularly true for aerosols collected on organic filters. As discussed earlier, a major fraction of any aerosol will be organic matter, carbon, sulfate, nitrate or ammonium, none of which produce significant gamma activity. The inorganic fraction, mainly consisting of the oxides of Ca, Fe, Si and Mg, plus P and Cl again produce low or short-lived activities. Sodium and bromine can be a problem in some marine aerosols and this may require a delay in counting until the ^{24}Na activity has decayed to an acceptable level, usually a few days after irradiation. Such a delay time precludes the analysis of any short-lived trace elements by this technique. In general, two irradiations are carried out as for most other types of environmental sample. A short irradiation (1–5 min duration depending on the available neutron flux) uses a rabbit system for the short-lived nuclides of Al, Ca, Cl, Cr, Cu, Mg, Na and V. This may also include CINAA for the determination of the very short-lived nuclides (<10 s) ^{38m}Cl, ^{77m}Se, ^{185m}W and ^{207m}Pb. These are then followed by a long irradiation (2–8 h, again depending on the flux) and several counting periods at different decay times for the remaining long-lived elements. In this way some 33 elements (Al, As, Ba, Br, Ca, Ce, Cl, Co, Cr, Cs, Cu, Eu, Fe, Hf, Hg, K, La, Mg, Mn, Mo, Na, Pb, Rb, Sb, Sc, Se, Sm, Sn, Sr, V, W, Zn and Zr) can be determined with DLs ranging from 4×10^{-4} ng m^{-3} for Eu to 30 ng m^{-3} for Ca and Cl, based on filtering 1000 m^3 of air and irradiations with a flux of $\sim 2 \times 10^{17}$ nm^{-2} s^{-1}. A more complete set of DLs is given by Kolthoff et al.[53]

These data are based on the normal multielement comparator technique. Some data have also been published based on the single comparator method which reduces the analysis time of the standards considerably. It has also been shown that the k_0 method gives reliable results for suitable air particulate reference materials and has been used in some air pollution studies. A few more elements (Ag, Au, F, In, Ta, Th and U) are better determined by ENAA. Also, Landsberger and Wu[54] showed that ENAA in conjunction with a Compton suppression γ-ray detection system gave improved DLs for As, Cd, I, Mo, Sb, Si, and U, with a particularly low DL for iodine. Finally, we have already mentioned that F is probably best determined by the ^{19}F(n,α)^{16}N reaction using 6 MeV neutrons from an accelerator in conjunction with a rabbit system.[29]

The use of low-energy photon spectrometry (LEPS) i.e. photons in the range 50–200 keV has also been investigated for use with both INAA and ENAA. The technique, however, does not markedly add to the list of elements that can be determined using INAA beyond the lanthanides Lu, Sm, Tm and Yb and an advantage for the determination of Cu. In combination with ENAA, it improves the sensitivity for the determination of Br, Co, In, Sb and V.

FNAA plays a minor role in air particulate analysis. In general, it is confined to the determination of the matrix elements (Al, Ca, Cl, Fe, Mg, Mn, Si and Ti). In a few laboratories where high fluxes of 14 MeV neutrons are available ($\sim 5 \times 10^{12}$ n s^{-1}) it is possible to determine

a number of trace elements although, again, the range compared with INAA and ENAA is not extended and the small sample weight militates against low DLs.

RNAA also plays little part in air particulate analysis. This is partly due to the fact that monitoring air pollution requires the analysis of large numbers of samples fairly rapidly but also due to the problems of sample size and dissolution.

Accuracy and precision are problems in any type of analysis. For INAA, the problems associated with the technique are well known and in most circumstances lead to a precision of $\sim\pm 1-2\%$. For air particulate analysis, the largest error probably arises from the inhomogeneity of the sample; however, as long as the entire sample is subjected to analysis, this should not detract from the normal precision of the technique. Kist et al.[52] revealed differences in the concentration of elements such as Au, Br, Cl, Hg and W determined by their passive absorption method compared with samples obtained by the standard filtering methods. This was ascribed to the fact that these elements exist in a thin particulate or a vapor-gas phase which are only sampled with poor efficiency by the use of standard filters.

5.5 Applications

5.5.1 Direct Methods of Analysis

A large number of studies of air pollution and related studies have certainly been undertaken since about 1985. The majority of these apply to the monitoring of the air in specific urban areas with some data from adjoining rural areas to provide a comparison. Alternatively, a number of studies have also been concerned with the analysis of the emissions in the neighborhood of incinerators, smelters and power stations since these can be the sources of large quantities of particulate (some of it PM10) and other toxic components, both inorganic and organic. In the earlier phases of these studies most of the effort was confined to the developed world. A number of such studies are detailed by Alfassi[3] in Chapter 13 of Volume 2 of his book and in an earlier review by Alian and Sansoni.[55] However, attention has shifted to areas such as southeast Asia since their rapid economic rise has been accompanied by that of severe air pollution. Studies have shown that of the 15 cities with the highest total particulate matter in their air, 12 of these are in Asia. This has stimulated an IAEA CRP in the Asia and Pacific region. Determinations of large numbers of trace elements in air particulates on filters by a combination of methods, including INAA, can be used as internal checks on the quality of data. Such consistent data can then be reliably used for receptor model analyses.

Fly ash from power stations is a particular problem, being composed of the inorganic fraction of the fuel. Studies based on INAA and other techniques have shown that some toxic and radioactive species (e.g. As, Mo, Ni, Pb, Th, V and Zn) are concentrated significantly in this fly ash relative to their initial values in the fuel.[56] This process is exacerbated by adsorption on the fly ash of these components in the flue gas.

Studies on the quality of air in the workplace environment have become of increasing importance. A number of industries (e.g. metal plating, metallurgical processing, etc.) lead to the release of toxic metals and other pollutants into the local atmosphere. Equally, levels of pollutants in indoor public areas due to, say, tobacco smoking have become of concern. Analysis of filter samples of indoor air polluted by tobacco smoke using an ENAA technique revealed elevated levels of As, Cd and Sb, with consequential potential health risks beyond those normally associated with passive smoking.[57]

5.5.2 Indirect Methods of Analysis

Monitoring the ambient air by the methods discussed above has limitations, on both a geographical and a temporal scale. These are due to the necessity of setting up monitoring stations in suitable areas, which are expensive in themselves, and then the necessity for analyzing the samples collected. Such monitoring stations are not really suitable for covering wide geographical areas, particularly if remote areas with difficult accessibility are involved. Also, studies over a long time period (several years) can involve the analysis of a large number of samples, even from one station.

In these circumstances, another approach is taken, that of indirect monitoring. The majority of such monitoring usually involves sampling various types of plant materials which can retain the elements deposited on them from the atmosphere and thus act as monitors of the atmosphere in which they are growing. Such materials are referred to as biomonitors. Other, nonorganic materials such as snow have also been used as accumulators of atmospherically deposited trace elements.

Lichens and mosses have almost invariably been used in air pollution studies since these plants absorb elements directly from the air because they lack root systems. They also concentrate and retain the elements adsorbed. This is in contrast to vascular plants which take elements directly from the air and, more importantly, from the soils in which their roots grow. Hence, variations in element concentration cannot normally be directly correlated with changes in atmospheric concentration. An exception to this is the use of evergreen oak leaves to monitor vehicle pollution using both INAA and photon activation analysis (PAA) (for Pb).[58] These leaves were shown to be very good monitors for air pollution studies, particularly for Pb and a few other elements (Ce, Co, Eu, Hf, Sb and Zn),

which were shown not to reach the leaves through the tree roots. There was good correlation between Pb on the leaves and the level in the air.

Generally, however, lichens and mosses have been used as biomonitors. One of the most comprehensive studies using mosses was that by Steinnes et al.[59] Here a specific moss was collected from over 500 sites throughout Norway and the moss samples subjected to INAA, with some 22 elements determined. A further four elements were determined by flame AAS. The data from these studies allowed different sources of pollution to be identified varying from long-range atmospheric transport of pollutants from other parts of Europe to local sources within Norway. There was also an indication of atmospheric transport from the marine environment. Similar studies by Sloof and Wolterbeck based on lichens collected in the Netherlands were used to create geographical concentration patterns and to estimate the sources of pollution.[60] Analysis of lichens and mosses by INAA has also been used to investigate pollution around industrial plants such as smelters.

A more unusual example of indirect monitoring is that based on the analysis of snow.[61] The method is based on the fact that snow scavenges particulates from the air whilst larger particles sink into the snow and are immobilized in it. Samples of melted snow from the Montreal area of Canada were analyzed by INAA allowing enrichment factors to be determined and thus allocated to natural or anthropogenic sources.

6 ANALYSIS OF SOIL, SEDIMENTS AND COAL

6.1 Soil

Considering the importance of soil for the production of food, there has not been a vast number of analyses by either INAA or RNAA. For INAA it is usual to perform a short and a long irradiation, as in most areas of environmental analysis, and possibly two counting periods following the long irradiation. This results in the determination of up to 24 elements (Al, Ba, Br, Ce, Co, Cr, Cs, Dy, Eu, Fe, Hf, La, Lu, Mn, Na, Rb, Sb, Sc, Sm, Tb, Th, V, Yb and Zn) in most soils and a further 16 (As, Au, Ca, Cl, Ho, I, K, Mg, Nd, Sr, Ta, Ti, Tm, U, W and Zr) in many soils. This number is augmented by nine more elements (Ag, Cd, Gd, In, Ir, Mo, Ni, Pd and Sn) by use of ENAA although, again, a few of the elements determined by INAA are better determined by ENAA. Further elements such as Hg and Se can be determined by RNAA but this technique has not been widely used for soils.

A number of soil and sediment SRMs are available to act as multielement standards or as reference materials, with some having quite high concentrations of several trace elements. These are often suitable as standards in the analysis of soils and sediments polluted by heavy metals.

Soils have also been analyzed in attempts to study the mobility of heavy trace metals through them. This is of particular concern where sewage sludge, often containing high concentrations of heavy metals has been used as fertilizer, a growing practice in many countries. The potential mobility of these metals in soils is of concern and has been investigated using both INAA and ICPS (inductively coupled plasma spectroscopy). INAA is probably a better method owing to the presence of some metals that are located generally in minerals resistant to acid digestion and hence give low readings by the ICPS technique. The data indicate that, not surprisingly, different metals have different mobilities but that significant amounts of Cd, Cu, Hg and Zn remain in the topsoil up to 15 years after application of the sludge.[62]

Regional surveys of surface soils have also been carried out using INAA as well as other analytical techniques in order to construct accurate geochemical databases for environmental, agricultural and related purposes. Obviously, such surveys require the analysis of large numbers of samples for which INAA is admirably suited.[63] Similarly, baseline element concentrations have been determined for soils and some associated vegetation in a given region with the aim of investigating landscape patterns of the elements. Additionally, soils have been used as pollution monitors in regions where they are subject to potentially high concentrations of toxic elements.

A number of studies using INAA have also investigated the uptake and concentration of heavy metals by plants growing in normal or contaminated soils. This is of concern where plant material for human consumption is grown. An example was the concern for the levels of Cd in cabbages grown domestically in the southwest of England when the levels of Cd in the soil were found to be several times the local background level.

6.2 Sediments

By sediments we mean the material deposited at the bottoms of lakes, rivers, estuaries and seas. The techniques and elements that can be determined by INAA are very similar to those discussed for soils. In sediment analysis, however, a much greater emphasis is placed on determining element concentrations in sediment cores. Core samples are often obtained using a simple plastic tube, 2–5 cm diameter and up to a meter in length. The tube

is inserted into the sediment to obtain the core which can later be extruded from the tube. This core is then usually cut into sections (often 5 or 10 cm in length but shorter lengths for greater detail). Core sections, after drying (freeze drying preferred) and pulverizing can then be packaged for NAA. INAA, ENAA and FNAA have all been used to analyze sediment cores.

The core is essentially a historical record of the sediment with the age of the sediment increasing down the core; each cut segment then represents a specific time zone. Analyzing the segments reveals changes in the concentration of the elements with time and may reflect particular events in the history of the region. The total length of time represented by a single core obviously depends on the sedimentation rate, which itself may vary with time. A plot of change in concentration with core depth is known as a concentration–depth profile. In some cases the concentration–depth profile may reveal the sedimentation rate if it is assumed to be constant. Sodium concentration–depth profiles may reflect the change of sediment origin from lacustrine through brackish (possibly estuarine) and possibly even to marine for sediments found close to the sea. Cores taken from the sea bed adjacent to the outflow of a major river such as the Amazon or the Mississippi can distinguish the river sediments from those of marine origin and so can be used to investigate the factors controlling the discharge of river sediments into the ocean.

A number of countries (e.g. Canada, South Africa, UK) have also used INAA to analyze large numbers of samples obtained from lake and river sediments from throughout the country concerned again to provide regional geochemical databases.[63] These can help in the geochemical exploration for commercially viable mineral deposits and potentially useful regions can then be investigated in greater detail by geological investigation.

The method of activable tracers has also been used to investigate accretion, reworking and erosion of sediments. Suitable tracers are certain rare earth elements (Dy and Sm) and in one case a Cs-saturated phlogopite (a form of mica with exchangeable K) where the Cs replaced the K of the phlogopite.[64] In all cases the tracer is applied to the sediment. After a given period of time (ranging from days to years), the sediment is sampled and after activating the tracer, its concentration can be determined and used to investigate changes in the sediment.

Finally, studies of the transport and ultimate fate of pollutants can be studied by examining sediments from lakes or rivers. Analyses of such sediments is particularly useful for following the transport and ultimate fate of fertilizers washed out of fields and into rivers and lakes. Fertilizers of phosphate origin tend to have relatively high concentrations of the rare earth elements and this will result in increases of these elements in the lake or river sediments. INAA is a very sensitive method for the determination of most of the rare earths usually making it the preferred method in this type of study. Toxic elements such as As have been determined by RNAA in high concentrations in lake sediments as a result of the use of arsenite pesticides sprayed on to adjacent agricultural areas.

6.3 Coal

NAA has been widely used in coal analysis, much of it directed towards on-line analysis of bulk coal samples prior to their use in power or conversion (to liquid fuel or gas) plants. The other role of NAA in coal science is in the investigation of trace element concentrations and patterns.

Trace and minor element analysis of coal usually employs a short and long irradiation strategy, allowing for the determination of about 38 elements (Al, Ag, As, Ba, Cr, Ca, Ce, Cl, Co, Cr, Cs, Dy, Eu, Fe, Hf, I, K, La, Lu, Mg, Mn, Na, Nd, Rb, S, Sb, Sc, Se, Sm, Ta, Tb, Ti, Tl, U, V, W, Yb and Zn). In addition, B is sometimes determined by PGNAA. Coal SRMs are available to act as both multielement standards in INAA or to provide checks on the accuracy of analyses using other standards. Such analyses can serve a number of purposes.

One of these involves exploration and mining of coal where the trace element composition has been used to try to ''fingerprint'' coal seams. Most of these attempts, however, have not proved commercially viable owing to the large variations of trace element patterns within a given seam. More hopeful is the fingerprinting of certain formations that enclose a given seam.

Of more importance, however, is the use of trace element data to investigate the fate of volatile or more or less toxic elements when coal is burnt.[65] Trace elements in coals might be expected to follow the crustal abundance of such elements. This is found to be the case for many of the elements although some such as As, Br, Cd, I, Mo, Pb, S, Sb and Se are significantly enriched. Levels of S vary widely in coals and, because of its crucial role in the production of acid rain, levels have to be carefully monitored.

The combustion of coal releases significant amounts of trace elements either in the form of gaseous discharge (Br, Cl, I, S and Se) or as fly ash, particulate matter of varying dimensions, to the atmosphere. These releases are then studied as part of air pollution monitoring, as discussed in section 5 of this article.

The rest of the trace elements not released to the atmosphere are retained in the ash that remains at the end of combustion. It is found that most nonvolatile elements are considerably concentrated in the ash. The total ash formed depends on the initial inorganic (mainly

silicates) content of the coal. The disposal of this ash remains a major environmental problem since the total world annual output is hundreds of millions of tons. Most of this ash is disposed of by landfill or minefill. An important problem is the leaching of toxic elements from this material by groundwater and leaching studies based on INAA have been undertaken by Jervis et al.[66]

On-line analysis of coal has become increasingly important and activation techniques have predominated because they are nondestructive, can be automated and are capable of producing rapid results. Also, radioactivity induced in the coal by neutron irradiation is both short-lived and negligible. Coal analysis in this context is used to determine the ash (from the concentrations of Al, Fe and Si), sulfur, nitrogen (important for its role in affecting catalysis in coal conversion) and chlorine (high chlorine coals cause boiler corrosion) contents of coal along with its calorific value. The latter is not determined directly but is based on the carbon content of the coal.

At present, the favored approach to on-line coal analysis is based on PGNAA.[67] A fast neutron source (either isotope- or accelerator-based) is used and the neutrons thermalized within the coal to allow neutron capture necessary for PGNAA. For on-line situations radioisotope sources offer many advantages over accelerators, being physically small, rugged, not requiring any external power or maintenance and having long useful lifetimes. The sources most generally used are ^{252}Cf and ^{241}Am/Be.

Unfortunately, the measured intensity of any capture γ-ray peak is not directly proportional to the element concentration as it also depends on the thermal neutron flux in the sample, which is itself dependent on the concentrations of all the elements in the sample and, in particular, small concentrations of B or Cl. On the other hand, the ratio of one capture γ-ray peak area to that of another is directly proportional to the ratio of the elemental concentrations. Therefore, if one capture γ-ray-producing element can be absolutely determined by a separate technique, a quantitative assay of all the other capture γ-ray producing elements can be made. Fortunately, this is possible in the case of hydrogen whose absolute determination can be made based on the measurement of the epithermal neutron flux escaping from the coal. This then allows for the determination of Al, C, Cl, Fe, N, S and Si by the peak ratioing technique.

Two problems still remain with on-line analysis based only on PGNAA. The first is that although C can be determined by detection of the prompt γ-rays, the method is severely limited by the small (n,γ) cross-section, so that the precision of the determination is poor. The second and more important problem is that PGNAA does not allow for the determination of O because its capture cross-section is extremely small and detection of subsequent γ-rays is almost impossible. Thus determination of *O* is only possible by difference, which involves the determination of the concentration of all the other major elements and the difference from 100% is assumed to be oxygen. This is the method that must be used in all other techniques for coal analysis.

Both problems are solved by the use of inelastic scattering reactions to produce γ-ray peaks. Here a ^{241}Am/Be source must be used because of its ability to excite more noncapture reactions than ^{252}Cf. Thus, C is determined from the 4.43 MeV γ-rays resulting from the ^{12}C(n,n$'\gamma$) inelastic reaction. Oxygen is determined indirectly using the ratio of C to O peak areas produced in the inelastic scattering reactions on the two elements (6.13 MeV γ-ray from ^{16}O(n,n$'\gamma$)). Since carbon can be determined either by PGNAA or absolutely using the inelastic scattering peak (to an accuracy of $\pm$10%), this gives a method for the determination of oxygen. The disadvantage is that large expensive NaI(Tl) (thallium-activated sodium iodide detector) crystals must be used, which are also susceptible to vibration and thermal shock making them unsuitable for on-line purposes.

7 ROLE OF NEUTRON ACTIVATION ANALYSIS IN SPECIATION STUDIES

7.1 Introduction

An important aspect of the analysis of trace elements in environmental samples is that of speciation. Speciation analysis can be defined as the concentration of an element in each of the physicochemical forms present in the system and which together represent the total concentration of that element. For example, natural waters usually contain some particulate or colloidal material so that a particular element may be present in solution or bound to the particles or colloids. A similar situation exists for other environmental samples such as air, where we have already seen that particulate matter is present, and in biological systems. The presence of different species (maybe in different oxidation states) of an element will affect a number of environmental parameters, such as its mobility, transport, bioavailability and toxicity.

NAA by itself cannot distinguish between the various species in which the element may be found; however, in combination with other analytical techniques it may be used very effectively in speciation analysis. The most important of these other analytical techniques are various separation methods which bring about the isolation of the respective fractions or forms which can then each be analyzed by the available NAA techniques.

7.2 Speciation of Elements in Water

There is a gradation in size between simple molecules present in solution and macroscopic particles rather than abrupt changes. It is important, therefore, that the method adopted for size fractionation does not itself disturb the original distribution. Size fractionation methods based on both filtration and ultrafiltration are commonly applied. For ultrafiltration, where the aim is to isolate the low-molecular-weight (low-MW) species, dialysis, the use of hollow-fiber cartridges or a series of ultrafilter membranes are usually the preferred methods. Hollow-fiber cartridges have the advantage that the species do not absorb on the fibers to any great extent. Cartridges with MW cut-off of 10^3, 10^4 or 10^5 are simply placed in the water and the species of mass below the particular MW cut-off are filtered through. Similarly, a series of filters and ultrafilters may be used to separate both larger, suspended particles and then successive MW fractions down to as low as MW 500. This ultrafiltrate can then be collected directly in polythene irradiation vials along with the the solid on the filter for INAA. Alternatively, a polythene container is used to collect the filtrates if RNAA is necessary. Analysis by INAA can give information for up to about 40 elements in many cases Thus, it is possible to show the major forms in which these elements exist in water, e.g. alkali metals occur mainly as free cations, Al, Au, Sb, U and V mainly as hydroxy complexes whilst other elements such as Co, Cr, the lanthanides, Ni and Zn tend to form soluble organic and inorganic complexes.[68] In addition, the size distribution pattern of a large number of elements can be readily investigated.

Water containing fulvic and humic acids (complex organic material) would be expected to give rise to organic complexes of several elements. One way to investigate such complexation would be to decompose the organic matter prior to ultrafiltration so that the complexed elements are released back into solution. The destruction method must ideally be capable of operating in situ and a candidate is γ-irradiation.[68] The elements are again determined by INAA following γ-irradiation of the water and ultrafiltration. In this way it can be shown that the dissolved species of Co, Cr, Ho, Lu, Ni, Sc, Tm and Yb predominately exist as soluble organic complexes, whereas Ag, Ce, Eu, Fe, La and Sm are chiefly associated with organic colloids.

For elements such as As, Cr and Sb, where their toxicity and biological activity depend on their oxidation state it is important to differentiate between species in different oxidation states. In order to do this some form of chemical separation is essential. We have already referred to the possible separation of As(III)/As(V) and Sb(III)/Sb(V) on MgO (section 4.3). The oxidation states of Sb can also be separately determined by INAA by use of the fact that only Sb(III) is extracted into a chloroform solution of APDC. Similarly, As(V) may be determined by its complexation with molybdate followed by coprecipitation with tetraphenylphosphonium chloride, with any As(III) present first removed with dibenzyldithiocarbamate.[69] Finally, Cr(III) and Cr(VI) can be separated based on the variation of the coprecipitation yields with $Pb(PDC)_2$ as a function of pH, with Cr(VI) coprecipitated at pH 4.0 but Cr(III) only at pH 9.[70] INAA of the precipitate thus yields the concentration of either species directly. Similarly, iodide and iodate speciation in water can be determined following preconcentration on bismuth thionalide.[71] Following irradiation of the precipitate, kinetic differences are exploited in the isotopic exchange of iodide and iodate with iodine in chloroform solution, since the isotopic exchange of iodide occurs almost instantaneously but that for iodate is very slow.

7.3 Speciation of Elements in the Atmosphere

One method that has been used is based on the analysis of rain water.[72] The rain water is filtered through a membrane to collect the solid particulate matter whilst the soluble trace elements are collected in the filtrate. The filtrate is dried to form a solid and both this and the solid collected on the filter are irradiated and elements determined by INAA. In this way, a crude estimation can be made of the trace elements present in the particulate matter and those present in the vapor-gas phase. Based on such experiments it was concluded that Au, Br, Cl, Cr, Cs, Fe, K, La, Mn, Se and Sm are found in the particulate fraction whereas As, Hg, Sb and Zn occur mainly in the vapor-gas phase.

A method for separating particulate, inorganic and organic forms of iodine in the air has also been described.[73] The particulate matter was collected in the usual way by filtration through a membrane filter. Inorganic iodine was collected by passing the air through two filters impregnated with lithium hydroxide and organic iodine in two beds of chemically treated activated charcoal. The filters or activated charcoal were then irradiated and ^{128}I counted. Results showed that almost 90% of the atmospheric iodine was in gaseous form in which the organic form dominated.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectroscopy
AC	Activated Carbon
APDC	Ammonium Pyrrolidine Dithiocarbamate
CINAA	Cyclic Instrumental Neutron Activation Analysis

CRP	Coordinated Research Program
DL	Detection Limit
EC	Elemental Carbon
ENAA	Epithermal Neutron Activation Analysis
FES	Flame Emission Spectroscopy
FNAA	Fast Neutron Activation Analysis
HAP	Hydrated Antimony Pentoxide
IAEA	International Atomic Energy Agency
ICPMS	Inductively Coupled Plasma Mass Spectrometry
ICPS	Inductively Coupled Plasma Spectroscopy
INAA	Instrumental Neutron Activation Analysis
LEPS	Low-energy Photon Spectrometry
MIBK	Methyl Isobutyl Ketone
MS	Mass Spectrometry
MW	Molecular Weight
NAA	Neutron Activation Analysis
NaDDC	Sodium Diethyldithiocarbamate
OC	Organic Carbon
PAA	Photon Activation Analysis
PAN	1-(2-Pyridylazo-2-naphthol)
PDC	Pyrrolidine Dithiocarbamate
PGNAA	Prompt Gamma Neutron Activation Analysis
PM10	Particles with Aerodynamic Diameter Less Than 10 μm
RNAA	Radiochemical Neutron Activation Analysis
SRM	Standard Reference Material
TAN	1-(2-thiazolylazo)-2-naphthol

Nitroaromatic compounds (NACs) are important anthropogenic chemicals, which may enter all areas of the environment in significant amounts. Once there, they may be transformed, mainly via redox reactions. Most NACs and their transformation products are rather toxic, both in humans and ecosystems, and they are especially known for their carcinogenic potential. Thus, input and detrimental effects of NACs make environmental surveillance necessary, which in turn requires selective, sensitive, unbiased and robust methods suitable for the analysis of complex mixtures. These requirements are mainly fulfilled by the combination of an enrichment step with chromatographic separation and use of an appropriate detector. Official methods today use liquid–liquid extraction (LLE) or solid-phase extraction (SPE), followed by high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection, or gas chromatography (GC) with electron capture detection (ECD). These methods are widely established and have been thoroughly tested in interlaboratory comparisons. However, new methods for extraction, separation and detection are emerging, which are superior in terms of the required characteristics, and thus may replace the existing methods in the future. Both standard methods and new developments for the environmental analysis of NACs are discussed in this article. Regarding the references given, priority was given to the most recent developments, and thus about 70% of the cited literature is less than five years old.

1 INTRODUCTION

For decades, NACs have been among the most widely used anthropogenic chemicals. Nitration of aromatic compounds is one of the key industrial processes, since the nitro group offers a variety of further functionalizations. Thus NACs are used as solvents, pesticides, explosives and fragrances and are intermediates in the production of pharmaceuticals, dyes, polymers, whitening agents and photochemicals.[1] Seventy NACs are currently listed as OECD (Organisation for Economic Co-operation and Development) high-production-volume chemicals, with a production of more than 1000 t per year in at least one member country. Of the parent compound nitrobenzene alone, 740 000 t were produced in the United States in 1994, mainly as a source for aniline. Emissions of NACs can occur during the production, the use and the disposal of the compounds. The Toxics Release Inventory of the United States Environmental Protection Agency (USEPA) estimates that the total emission of nitrobenzene to the environment in the United States was 320 t in 1997. In 53 of the USEPA Superfund Sites NACs are contaminants of concern. In addition to direct emissions, it has become obvious in recent years that NACs may also be formed in the atmosphere due to the reaction of nitrogen oxides with aromatics. This reaction is important both for polycyclic aromatic hydrocarbons (PAHs) to yield nitro-PAHs[2] and for benzenes to yield mainly nitrated phenols.[3]

There are hardly any naturally occurring NACs. One exception is aristolochic acid (Figure 1), which was used as a drug ingredient before its toxic effects were known. The molecular formulae of some important NACs are given in Figure 1. It can be seen that many compounds have more than one functional group governing their

Figure 1 Molecular formulae of selected NAC.

behavior, therefore some of the compounds may also be covered in other articles.

Table 1 gives the CAS no. and some important properties of nitrobenzene, 2,4-dinitrotoluene and the compounds shown in Figure 1. As might be expected from the diversity of the compounds, their physicochemical properties differ widely. In general, NACs are electron-acceptor compounds and the acidity of aromatic acids is much increased because of the electron-withdrawing nitro group. The introduction of a nitro group does not significantly alter the water solubility of nonionogenic compounds. Many NACs are known to be highly toxic and are proven or suspected carcinogens.[5,6] In contrast, the easily water-soluble nitrosulfonic acids do not show significant toxicity. However, their mobility and persistence in water make them possible drinking-water contaminants. A very common reaction in soil and water is the abiotic or biotic reduction of the nitro group to an amino group via three two-electron transfer steps. The corresponding anilines, which may be of even more environmental and toxicological concern, thus have to be considered in many cases. An extensive treatment on biodegradation of NACs can be found in the book by Spain.[7] The complexity of wastewater generated during the manufacture of trinitrotoluene was demonstrated by Spanggord et al.[8] Rosenblatt et al.[9] showed the multitude of products from phototransformations of NACs, including for the first time nitrobenzoic acids resulting from photooxidation of the methyl group. Recently, these and other ionic compounds were found in groundwater[10,11] and soil[12] samples, which suggests other mechanisms in effect besides photooxidation. In summary, most NACs require monitoring due to their high production, their toxicity and their behavior in the environment.

2 OFFICIAL METHODS OF ANALYSIS

To the best of our knowledge, NACs are not included in legislatory regulations as such. However, there might be regulations resulting from the use of specific NACs, e.g. as pesticides. These are not discussed further here since they are covered in other articles. Furthermore, the USEPA has issued health advisory levels for several explosive-related NACs, which are given by Tomkins in **Explosives Analysis in the Environment**. Despite the lack of general regulations, maximum NAC emissions from factories and contents in water and soil at former industrial sites might have been specified. For example, at the former ammunition plant in Stadtallendorf, Germany, remediation aims of 20–80 mg NAC per kg soil, depending on the proposed use of the area, were constituted by regional authorities.

Official methods of analysis for NACs are available for the determination of explosives, dinitroaniline pesticides and for a number of NACs in a general analytical scheme for semivolatile compounds. Table 2 briefly summarizes these methods.

As shown in Table 2 the official USEPA method 8030 has also been adopted for water analysis. Sample preparation involves a salting-out assisted solvent extraction with acetonitrile, as developed by Leggett et al.[13] In the new draft method 8095 this procedure is replaced by SPE which needs considerably less organic solvent. The official method requires primary analysis on a C_{18} column with confirmation on a second CN column since a single-wavelength UV detector is used.

Both the German DIN method 38407-17 and the USEPA draft method for explosives utilize GC for separation. The USEPA method includes even very

Table 2 Official methods for the analysis of NACs

Method	Analytes	Matrix	Sample preparation	Separation and detection
USEPA SW 846/8030 (http://www.epa.gov/SW-846/8330.pdf)	14 explosives-related compounds, including 12 NACs	Soil (also adapted for water)	Ultrasonic extraction with acetonitrile (soil); salting-out extraction with acetonitrile (water)	HPLC/UV
USEPA draft 8095	17 explosives-related compounds, including 13 NACs	Soil/water	Acetonitrile extract (soil); SPE with Sep-Pak™ C18 according to USEPA SW 846/3535 (water)	GC/ECD
DIN 38407-17	12 explosives-related NAC	Water	SPE with RP18 or LLE with toluene	GC/ECD or GC/PND
USEPA 627	Dinitroaniline pesticides	Wastewater	LLE with dichloromethane	GC/ECD
USEPA SW 846/8270 (http://www.epa.gov/SW-846/8270c.pdf)	Organic compounds, including at least 21 NACs	Soil/water	According to USEPA 3500 methods	GC/MS
USEPA TO-4	Organic compounds, including parathion and trifluralin	Air	Sampling of 288–403 m^3 air on filters	GC/PND or GC/ECD

DIN, Deutsches Institut für Normung; GC/ECD, gas chromatography/electron capture detection; GC/MS, gas chromatography/mass spectrometry; PND, phosphorus–nitrogen detector.

thermolabile nitramines and is therefore carried out on a short, wide-bore column (6 m × 0.53 mm) of low polarity (DB™-1 or DB™-5 or equivalents) for primary analysis and a mid-polar column (RTX™-200 or RTX™-225 or equivalents) for confirmatory analysis. The DIN method also requires a confirmatory analysis on a column of different polarity, but the recommended columns have an internal diameter of 0.2–0.4 mm and a length of 20–60 m. Suggested stationary phases range in polarity from DB™-1 to DB™-1701 or equivalents.

The standardized methods can help the practitioner in the fast establishment of a new method and are often required by regulatory bodies. The main advantage of these methods is the assurance of data quality by thorough testing and interlaboratory comparisons.[14] However, it should be emphasized that their use also poses some problems. Usually, the standardization requires several years before being officially adopted. Considering the rapid developments in the area of instrumental analysis they therefore often demand the use of rather outdated methods or equipment. As an example, USEPA method 8030 for the analysis of nitroaromatic explosives in soil and water is discussed here. The processing of water samples requires the use of salting-out extraction with 175 mL acetonitrile per sample. Some 97% of the acetonitrile remains in the aqueous phase and has to be disposed of with the sample. Furthermore, the extraction is very time-consuming, requiring several extraction/back-extraction steps. Modern SPE methods are able to provide at least comparable extraction efficiencies with much less solvent and time consumption. For soil samples an 18 h acetonitrile extraction in an ultrasonic bath is used. Here it has already been shown that faster methods such as accelerated solvent extraction (ASE) or supercritical fluid extraction (SFE), which are rather easy to automate and consume little solvent, are applicable. Nevertheless, none of these methods are included in the new draft method of the USEPA. In the determination step a primary column with an internal diameter of 4.6 mm is recommended. Again, it has been known for a long time that 4- and even 3-mm columns can be used with almost all HPLC equipment, providing even better separation in many cases, with much less consumption of the mobile phase. Loadability of the smaller columns is lower but in general this is not a severe problem in environmental analysis. Detection is done with a single-wavelength UV detector at 254 nm. To confirm positive results therefore requires a second column of a different selectivity. However, in most HPLC laboratories nowadays a diode-array detector (DAD) is in use which allows the on-line confirmation of peak identity with the comparison of UV spectra. This of course requires much less time than a second run for the same sample. Because of the drawbacks of the official method, several method adjustments were recently published to improve its performance.[15,16]

The USEPA method was selected as an example for outdated procedures because it is still in use worldwide,

but, as already mentioned here, the general problem exists for all standard methods.

3 SAMPLE PREPARATION

3.1 Water

3.1.1 Sampling and Storage

Water samples should be taken in precleaned brown-glass bottles. Bottles and stoppers should be rinsed several times with the sample on-site. Since some of the analytes are volatile the bottles should be filled completely, without leaving a headspace. Extraction of water samples should be done as soon as possible after sampling. If storage cannot be avoided the samples should be stored at temperatures below 4 °C. Even then losses are possible with prolonged storage times. The loss is mainly due to microbial degradation, hence the stability is enhanced if growth of microorganisms is inhibited. For that purpose, sodium azide and mercury(II) chloride are mainly used, but the use of mercury salts is not recommended due to problems with the disposal of the samples after processing. A 1-mL portion of a saturated solution of sodium azide in water is sufficient to depress microbial activity in a 1-L sample.

3.1.2 Extraction

A brief overview of important characteristics of some extraction techniques for aqueous samples is given in Table 3. More detailed information can be found in the following sections and the cited literature.

Liquid–Liquid Extraction Several solvents are suitable for LLE of NACs. Most often, toluene (as in DIN 38407-17) and dichloromethane (as in USEPA method 625) are used.[17] In general, the choice between the two is partly determined by the detection method. For GC/ECD, toluene has to be used, while for the GC/MS and HPLC methods, dichloromethane is preferred (for HPLC this is because solvent exchange is easier with the more volatile dichloromethane). In the DIN method the extraction is done with two portions of 20 mL toluene (with 10 min of shaking in a separatory funnel) for a water sample of 1 L after adjusting the sample pH to between 6 and 8. In contrast, the dichloromethane extraction is done after salting-out of the sample with 100 g sodium chloride (for 1 L water). It is then extracted three times with 50 mL dichloromethane. In both cases, the extracts are dried over anhydrous sodium sulfate, filtered and reduced in volume under reduced pressure. Alternatively, the approach of Leggett et al.[13] (as used in the adaptation of USEPA method 8030 for water) might be used. They extracted with acetonitrile and achieved a phase separation between water and acetonitrile with the addition of high amounts of salt (see section 2). A general disadvantage of all LLE procedures is the use of rather high amounts of organic solvents, especially when more polar degradation products have to be included. An attractive further development in LLE is the use of a micro-extraction technique as described by Welsch and Block,[18] who found satisfactory recoveries (>70%) for nitroaromatic explosives and reduction products with the use of only 4.5 mL methyl *tert*-butyl ether in a multiple extraction scheme. Limit of detection (LOD) values given were in the low parts per trillion (ppt) range for di- and trinitroaromatics and in the high ppt range for mononitroaromatics.

Solid-phase Extraction SPE has increasingly replaced LLE in the analysis of NACs in water over the last decade. This is due to the reduction in organic solvent use, the high recoveries obtained in many cases, the ease of sample clean-up and the possibility of coupling SPE on-line with chromatographic separation. SPE procedures are included in both the DIN method and the new USEPA draft method for NACs in water. In both cases a C_{18} phase is used for that purpose. As an example, the DIN method is described in more detail here. A 2-g sample of the solid phase (for 1 L sample volume) is conditioned with 15 mL of methanol and washed with 15 mL of water.

Table 3 Characteristics of extraction procedures for aqueous samples

Method	Typical sample volume (L)	Typical extraction time (h)	Solvent consumption (mL)	Cost of equipment (apparatus/consumables)	Automation
LLE	1	1–2	40–200	++/o	−
Cartridge SPE	0.1–1	0.5–2	3–10	+/o	+
Disk SPE	1	0.3–1	3–10	o/−	o
SPME	0.01	0.2–1	0	+/+ (off-line) −/+ (on-line)	− (HPLC) ++ (GC)

SPME, solid-phase microextraction.

The water sample is salted out with 100 g of sodium chloride per liter of sample and the pH is adjusted to between 6 and 8. The extraction is performed with a flow of about 16 mL min^{-1}. Afterwards, residual water is blown off with nitrogen and the analytes eluted with 6 mL of ethyl acetate. If necessary, to achieve lower detection limits, the eluent is reduced in volume to 1 mL. C_{18} phases were described most often in experimental work carried out at the end of the 1980s and the beginning of the 1990s. However, their use in the analysis of NACs is already declining because of the commercial advent of polymeric phases, which offer higher capacities, a better retention of more polar compounds and enhanced pH stability, which is important for the analysis of degradation products. Styrene–divinylbenzene copolymers, which are available from most manufacturers of SPE materials, are mainly used for the extraction of NACs.[19] The extraction can easily be automated, as has been shown for explosives,[19,20] as well as for nitroaromatic pesticides.[21] Solid phases in disk geometry allow higher flows than packed cartridges and have less susceptibility to clogging, which are distinct advantages, especially for the extraction of large volumes of aqueous samples. In a recent monitoring study for selected pesticides (including NACs) in groundwater, a flow of 30 mL min^{-1} was used without breakthrough of analytes or pressure increase due to clogging.[22] Disk-type solid phases are already employed in the general USEPA method for performing SPE (SW 846/3535), and laboratories using cartridge types have to prove comparable performance.

An interesting new approach for the selective enrichment of NACs was described by Bucheli et al.[23] It is based on the interaction between electron-deficient aromatic rings and electron-rich clay minerals, which leads to the formation of electron donor–acceptor (EDA) complexes. These are strongest for polynitroaromatics, while for mononitroaromatics they are less efficient than the previously mentioned polymeric phases. The method has been proved to be suitable for routine analysis and on-line SPE.

Solid-phase Microextraction SPME is a relatively new, solvent-free extraction method that so far has rarely been described for the enrichment of NACs from water. However, there are reports on the extraction of nitrophenols,[24] dinitroaniline pesticides,[25] and several explosives, including trinitrotoluene and DNT, in seawater.[26] These reports have shown the potential of SPME, especially in conjunction with GC/MS. In general, SPME is still limited to GC separations in routine analysis and it requires the use of internal standards (preferably isotopically labeled ones) for accurate quantitation, because it is a nonequilibrium method.

3.2 Soil and Particulates

3.2.1 Sampling and Storage

A thorough treatment of the representativeness of soil sampling for explosives analysis has been carried out by Tomkins, **Explosives Analysis in the Environment**.[12] Briefly, a well-designed sampling plan is required to ensure the quality of spatially resolved information on contamination levels. Even inside a sample it is often difficult or impossible to obtain a homogeneous distribution of the analytes. Thus it is also important to make sure that a representative subsample is used for further analysis. Soil samples can be refrigerated without significant loss of analytes for several weeks but should be kept in the dark to prevent photodegradation.

For the sampling of particulates, high-volume air samplers are most frequently employed, which suck about 2000 m^3 air through a filter. The choice of an appropriate filter type is crucial in proper sampling.[27]

3.2.2 Extraction

There is a wide range of methods available for the extraction of soil samples. The classical approach is either extraction at elevated temperatures in a Soxhlet apparatus or mechanical shaking of the solid with an appropriate solvent. More recently, these methods have been partly replaced by extraction in an ultrasonic bath. These three methods and the use of a homogenizer–sonicator were compared by Jenkins and Grant[28] for the analysis of explosives in soil. They found extraction in an ultrasonic bath to be superior to the other methods. Lately, SFE and ASE have attracted considerable attention, and for some NACs there are applications for their use in extractions of solids. A brief overview of the important characteristics of some extraction techniques for solids is given in Table 4. More detailed information can be found in the following sections and the cited literature.

Soxhlet Extraction Even today, Soxhlet extraction is the standard method in many application areas, for example for the extraction of diesel emission particulates on filter paper.[27] Several solvents are commonly used, such as diethylether, dichloromethane, cyclohexane, and toluene. Recoveries are high for many compounds, but the temperature must be carefully controlled because many nitroaromatics are thermolabile. The distinct disadvantages of the Soxhlet method are its very high solvent consumption, usually 100–500 mL per sample, and the long extraction times needed (up to 48 h is common). The time of each cycle varies between 15 and 30 min.

Ultrasonic Treatment Ultrasonic treatment for the extraction of nitro-aromatic explosives was thoroughly

Table 4 Characteristics of extraction procedures for soil and particulates samples

Method	Typical sample mass (g)	Typical extraction time (h)	Solvent consumption (mL)	Cost of equipment (apparatus/consumables)	Automation
Soxhlet	5–20	2–48	100–500	o/−	o
Ultrasonic bath	5–10	1–18	5–50	o/+	−
ASE	5	0.5–4	10–50	−/o	+
SFE	5	0.5–1	1–2 (modifier)	−−/−	+

investigated by Jenkins et al.,[28,29] and shown to give reproducible results in an interlaboratory comparison.[30] As a result of these studies, the use of an ultrasonic bath in soil extraction became mandatory in USEPA method 8330 for explosives. In this method a 2 g subsample is extracted with 10 mL aceto-nitrile for 18 h. The fine particles are then flocculated with a calcium chloride solution (concentration = 5 g L^{-1}). After 15 min settling time the sample is filtered through a 0.5 μm filter. An internal standard should be added to the extraction solvent. In this method, acetonitrile is chosen as the extractant because of its better solvation of the nitramines, while, for the NACs, methanol gave comparable results regarding extraction efficiency. For other NACs, ethyl acetate, ethanol and dichloromethane have also been used. A general advantage of the ultrasonication technique is the possibility of processing several samples at the same time. A disadvantage is that it is not well suited for automation.

Accelerated Solvent Extraction In the past few years accelerated extraction from solids at elevated pressures and temperatures has been employed in many fields. Surprisingly there was only one report in the open literature on the use of this method for NAC extraction.[31] The authors compared six different extraction techniques for nitroaromatic explosives in real soil samples from a former ammunition plant. They found ASE with methanol to be comparable to standard methods in terms of extraction efficiency and reproducibility, but superior in terms of solvent consumption and extraction time. Saito and Yamaguchi[27] expect ASE to replace both Soxhlet and ultrasonic extraction for the analysis of particulates in the future.

Supercritical Fluid Extraction In contrast to the more recently introduced ASE, SFE employs mainly CO_2 as the extracting medium. CO_2 is chosen because of its favorable critical parameters (i.e. critical pressure 74 bar, critical temperature 32 °C) which help to keep it in the supercritical state. Lopez-Avila and Beckert prepared a thorough overview on the use of SFE in environmental analysis, including the extraction of 36 NACs from sand and a reference soil.[32] In the last few years the influence of different modifiers on the extraction efficiency has been intensively investigated.[33–35] For trinitrotoluene and trinitrobenzene Wujcik and Seiber[34] found the following conditions to be optimal: 5% methanol, 150 °C, 517 bar (7500 psi), 5 min static and 15 min dynamic extraction. Deuster et al.[35] emphasized that direct addition of the liquid modifier to the sample was superior to the use of premixed CO_2/modifier. Toluene and acetonitrile were comparable in enhancing the extraction efficiency of pure CO_2 for nine NACs, whereas methanol was less effective. The optimized conditions were: 2 mL modifier, 90 °C, 400 bar, 15 min static and 15 min dynamic extraction. SFE was also found to be suitable for the extraction of parathion and 4-nitrophenol from soil[36] and it is assumed that SFE should be similarly suited to the analysis of nitro-PAHs.[27]

4 METHODS WITHOUT ANALYTE SEPARATION AND IN SITU TECHNIQUES

4.1 Chemical Methods

Numerous chemical reactions of NACs leading to colored products are described in the literature. Such reactions are the basis for spot tests, spraying reagents for thin-layer chromatography (TLC) and titration procedures. Several spot tests on NACs are described by Jungreis and Ben-Dor.[37] The principles of the tests are: transformation of a polynitroaromatic with strong base to a highly colored Jackson–Meisenheimer anion or quinoidal form (Janovsky reaction); derivatization with phenylacetonitrile in an alkaline dimethylformamide (DMF) medium to a blue- or yellow-colored addition product; formation of a charge-transfer complex with *N*,*N*-diethylaniline.

Of these, only the Janovsky reaction has so far been employed in environmental analysis. A procedure reported by Medary[38] uses methanol as the extraction solvent for soil samples. The absorbance of the purple color produced by addition of sodium hydroxide to the soil extracts is measured at 516 nm and found to be directly proportional to the concentration of trinitrotoluene. The estimated detection limit of the method is 4–8 ppm.

The same reaction was utilized for a field-test kit for trinitrotoluene allowing semiquantitative measurements.[39] To achieve this, small glass columns are filled

with a polystyrene-based anionic exchanger with a thin layer of a solid base (NaOH, CaO or MgO) on top. In the field, 5–50 mL of water or a methanolic soil extract is injected with a disposable syringe. The colored Jackson–Meisenheimer anions are formed in contact with the base and extracted with the anion exchanger. The length of the colored zone in the column differs depending on the amount of trinitrotoluene present. As might have been expected, there are a number of interferences, for example due to other organic or inorganic anions in varying concentrations.

The adaptation of the Janovsky reaction to an automated sequential injection system was recently reported for the rapid quantitative determination of TNT in soil.[40] Acetone extracts of the soil samples were injected with a reagent solution of potassium hydroxide and sodium sulfite into a carrier stream (acetone/water 88/12). After a reaction time of 30 s the mixture was dispensed by the carrier through a flow cell of a spectrophotometer and the absorbance was measured at 470 nm. It was shown that the method is selective for TNT and had only little or no response to mono- and dinitroaromatic compounds. The detection limit was 0.5 $\mu g\,mL^{-1}$ trinitrotoluene in solution.

Another possibility for a spot test is the facile reduction to the corresponding aromatic amines, which can subsequently be derivatized to form highly colored azo dyes.[41] If the dyes are extracted with *n*-butanol a semi-quantitative colorimetric or photometric measurement is possible.

The general advantage of such simple chemical methods is their quick and easy use in the field, which allows a sound selection of samples for further analysis. However, due to their low specificity and sensitivity, their use will be limited to investigations on sites where rather high concentrations of NACs are found.

4.2 Electrochemical Methods

Determination of NACs by electrochemical methods utilizes the reduction of the nitro group. Depending on the pH of a solution, the reduction leads to the corresponding hydroxylamino compounds or anilines, which require 4 e^- or 6 e^-, respectively, for each nitro group. Thus polynitroaromatics in particular can be very sensitively detected, a technique which is also used in electrochemical detectors in HPLC (see section 5.2). With differential pulse polarography (DPP) and adsorptive accumulation methods, detection limits in the low $\mu g\,L^{-1}$ range are achievable. Voltammetric methods have been intensively investigated for the determination of NACs, but there are few applications in environmental analysis. Recently, it was shown that with DPP tri-, di- and mononitrotoluenes can be distinguished due to their different reduction potentials.[42] After minimizing the differences in reduction potentials of positional isomers, this method was used to establish a sum parameter for rapid determinations in process water from a treatment plant for contaminated soil. The principle of the method is shown in Figure 2. Firstly, the concentration of TNT is calculated from H_{SI} by comparison with a TNT standard H_{PI}. The contribution of this TNT concentration to SII is calculated and subtracted from the overall peak height to yield H_{SII}, which gives the concentration of DNTs. The same procedure is repeated for SIII and the mononitrotoluene concentration is calculated from H_{SIII}. Method validation with a standard HPLC method showed good agreement of the results.

Figure 2 Voltammetric detection of nitrotoluenes. Reduction at different potentials allows quantification of tri-, di- and mononitrotoluenes. SI to SIII: sum peaks for tri-; di- and tri-; mono-, di- and trinitrotoluenes, respectively. H_{SI} to H_{SIII}: peak height for tri-, di- and mononitrotoluenes, respectively. (Adapted from Weibels[42] by permission of Görich & Weiershäuset, Marburg.)

4.3 Immunoassays and Sensors

Immunochemical methods have been successfully used in biochemical and biomedical analysis for many years. In the last decade they have received increasing acceptance in environmental analysis. Enzyme-linked immunosorbent assays (ELISAs) are generally faster and less expensive than conventional analytical methods and require only simple equipment. They are highly specific and can be used without or only minimal sample clean-up and are therefore especially suited for field screening tests.

The procedure for a heterogeneous ELISA involves the following steps. First the surface of the test device, in most cases a microtiter plate coated with an analyte antibody, is incubated with the analyte solution and an analyte–enzyme conjugate. In a competitive reaction both can bind to the antibodies on the surface. After a specific reaction time, the system is washed to remove unbound molecules. In the next step the enzyme substrate is added, which is converted to a colored reaction product by the enzyme of the bound analyte–enzyme conjugate. The intensity of the color is inversely proportional to the concentration of the analyte and can be determined photometrically.

Several immunological assays have been developed for the determination of the explosive TNT. A strategy for the validation of commercially available immunoassay test kits is described by Krämer.[43] Eck et al.[44] reported the development of assays for 1,3-dinitroaromatic compounds. The limits of detection for 2,4-DNT, 2,6-DNT, 1,3,5-trinitrobenzene and TNT were $1\,ng\,mL^{-1}$. No cross-reactivity with mononitroaromatic compounds was observed. 4-Nitrophenol and monosubstituted 4-nitrophenols can be determined with an ELISA at levels as low as 0.2 ppb (parts per billion) in water samples without extraction and clean-up.[45]

Keuchel et al.[46] described the development of a sensitive and selective immunoassay and its application for screening of TNT in groundwater. The method has a detection range from 40 ppt to 10 ppm for TNT in water, while di- and mononitroaromatic compounds show cross-reactivities below 2%.

A rapid immunofiltration assay was developed especially for on-site testing, allowing the determination of TNT in water and soil samples within an assay time of about 6 min. The test shows a quantitative color response to concentrations ranging from 1 to $30\,\mu g\,L^{-1}$ TNT in water and $50–1000\,\mu g\,kg^{-1}$ TNT in soil.[47]

Dosch et al.[48] used a homogeneous apoenzyme reactivation immunoassay system (ARIS) for the detection of TNT with a LOD of $5\,\mu g\,L^{-1}$. The system is less sensitive than heterogeneous ELISA methods, but faster and more simple, because it does not require any washing step.

NACs and their biodegradation products can be bound covalently to the organic matter of the soil. These bound residues are nonextractable with organic solvents and are therefore not detectable with common analytical methods. For the quantitation of such residues, immunoassays can be extremely useful. A first example in the literature is the use of a sandwich immunoassay to detect bound trinitrophenyl residues in polluted soil samples after exhaustive Soxhlet extraction.[49] The humic acid–analyte complex (bound NAC residue) is immobilized on the surface of the microtiter plate via nonspecific interactions with a basic protein. The bound trinitrophenyl fraction is then detected by a TNT-selective antibody. In the final step the bound TNT–antibody couples to an enzyme-labeled antibody. The color of the enzyme reaction is directly proportional to the amount of bound analyte.

Most immunoassays have been designed as highly specific methods with only minimal cross-reactivity. In screening tests, however, a high cross-reactivity is useful to detect the analyte, its metabolites and structurally related compounds. Broadening the antibody specificity offers the possibility of developing a group-specific assay for the analysis of 2,4,6-TNT, its precursors and metabolites in soils.[50]

Quantitation of 1-nitropyrene, which is suspected to have a high mutagenic and carcinogenic potential, in diesel soot and urban aerosols with an ELISA was investigated by Fröschl et al.[51] The cross-reactivities with several other NACs possibly present in air particulate matter were determined.

Numerous sensor systems for the detection of NACs, especially of trinitrotoluene, have been reported in the literature. Buttner et al.[52] describe the development of an amperometric sensor for the selective in situ detection and quantification of TNT and other nitrated explosives in soils. Thermal decomposition of the contaminated soil samples by a platinum wire heater (900 °C) produces volatile nitrogen–oxygen compounds which were detected with a sensitive amperometric gas sensor. The system has a detection limit of $0.5\,mg\,kg^{-1}$ for trinitrotoluene in soil.

An electrochemical sensor with rapid square-wave voltammetric scanning was used by Wang et al.[53] for the continuous monitoring of TNT in natural waters with low ppb detection limits. Fast detection of nitro- and aminoaromatic compounds with an electrochemical sensor system based on cyclic voltammetry was reported by Krausa et al.[54]

Several immunosensors have been developed for the detection of TNT on the basis of a competitive immunoassay (Shriver-Lake et al.,[105] Bart et al.[106]). A comparison of the detection limits, the assay time and the run-to-run stability of different sensor system is given by Narang et al.[55]

5 SEPARATION TECHNIQUES

The standard work on chromatographic methods for the separation of nitroaromatic and other explosives was published by Yinon and Zitrin in 1993.[56] Because of their experience, mass spectrometric methods and forensic analysis are emphasized in the book, whereas there is only a brief chapter on environmental analysis.

5.1 Gas Chromatography

Despite the limited thermostability of many NACs, separations with GC are possible without derivatization for all nonionic compounds. GC in fact is very popular for the analysis of all kinds of NACs. The reasons are the high separation efficiency compared with liquid chromatography, the range of detectors, and the ease of ''hyphenation'', especially with mass spectrometry (MS). Furthermore, the presence of the nitro group in analytes does not require the use of special columns, thus nonpolar polydimethylsiloxanes are widely used. However, especially in explosives analysis, short wide-bore columns are often used to prevent thermodegradation on the column. Thus, for example, the USEPA draft method employs a low-polarity $6\,m \times 0.53\,mm$ column for primary analysis. Besides, polynitroaromatics may be thermally degraded in the injector. Therefore the use of a filled liner is not recommended and the liner has to be replaced regularly. No single injection technique was found to be superior for all NACs. Methods in the literature comprise split, splitless, on-column and programmed temperature vaporizer (PTV) injection, depending on solvent type, sensitivity required and availability of instrumentation. If further functional groups are present, they will often determine the choice of column and injector. Yinon recommended the use of a cooled, temperature-programmable injector for the analysis of explosives, including DNTs and TNT, in water samples.[57] Large-volume injection of water into a PTV was used by Müller et al.[58] for the investigation of NACs. After evaporation of water and adsorption of the analytes from the gas phase, they are thermally desorbed in the PTV. An inherent disadvantage of this method is the very low injection rate due to the high enthalpy of vaporization of water, leading to prolonged analysis times.

A short overview of the most important GC detectors for NAC analysis is given in Table 5.

As for all organic compounds, FID may be used as the detection technique. But since a variety of more specific and sensitive detectors for NACs are available, it is seldom used today. In contrast, a modified instrument called a PND, or thermoionic detector (TID), which has an additional glass bead containing an alkali metal, is especially sensitive towards nitrogen- and phosphorus-containing compounds and is thus suited for the analysis of NACs. It is especially useful in the investigation of parathion insecticides, since these contain both elements,[59] but has also been used for the detection of nitro-PAHs in dichloromethane extracts of airborne particulates.[60]

Table 5 Comparison of detector types in GC

Detector	Instrument detection limits (pg)	Selectivity	Notes
FID	10–100	−−	Wide linear range
PND	1–100	o	Allows simultaneous detection of anilines, sensitivity increases with number of nitrogens
ECD	0.1–10	o	Linear range limited, sensitivity increases with number of nitro groups
TEA	10–100	++	Specialized detector for nitro and nitroso compounds, sensitivity increases with number of nitro groups
MS, EI, SIM	1–10	+	Sensitive detection requires SIM mode
MS, NCI, SIM	0.1–1	++	Sensitive detection requires SIM mode, quantification difficult, sensitivity increases with number of nitro groups

FID, flame ionization detection; TEA, thermal energy analysis; EI, electron impact; SIM, selected ion monitoring; NCI, negative chemical ionization.

From the number of publications, ECD seems to be the most popular detection technique for NACs besides MS. This is due to the ease of use and low cost of the detector, which provides adequate selectivity in many cases. The rather high electron affinity of NACs allows a sensitive detection. In general, the sensitivity increases with the number of nitro groups in the compound. A general disadvantage observed by many authors is the limited linear range of the detector. Examples of the use of ECD from the recent literature are for the determination of nitroaromatic pesticides in groundwater[22] and the analysis of nitroaromatic explosives in water samples.[61] The use of ECD is demanded in DIN method 38407-17 and USEPA draft method 8095. The DIN method alternatively allows the use of a PND, and a splitting of the column effluent to provide simultaneous detection is recommended.

The highest selectivity towards nitro (and nitroso) groups is shown by TEA. Since it is not a generally known

GC detection technique, its principle is described here briefly. After separation of the compounds the column effluent is pyrolyzed at 600–1000 °C. The decomposition leads to the formation of NO_2, which is catalytically reduced to NO. After passing a cold trap to remove interfering pyrolysis products, it is oxidized with ozone to yield electronically excited NO_2*. When relaxing to the ground state, light of wavelength 600 nm is emitted, which is detected by a photomultiplier. The use of TEA for the analysis of explosives was thoroughly discussed by Yinon and Zitrin.[56] Although TEA exhibits some unique features it is not widely used in environmental analysis. Probably this results from its high selectivity, which limits its use to nitro and nitroso compounds, and thus it is only available in specialized laboratories.

Maybe the most important detection technique in GC today, because of its general applicability along with its high selectivity, sensitivity and additional spectral information for compound identification or confirmation, is MS. With the standard EI ionization at 70 eV, radical cations are formed (M^+) which subsequently lose an oxygen radical $[M - 16]^+$ or, after rearrangement to the corresponding nitrite ester, nitrogen oxide $[M - 30]^+$. Loss of nitrogen dioxide is also favored, especially for nitrotoluenes, since a stable tropylium cation $[M - 46]^+$ can be formed. Nitrotoluenes are also a classical example of the ''*ortho*-effect'', which often allows the distinction of *ortho*-isomers from *meta*- and *para*-isomers. In *o*-nitrotoluene, interaction between a methyl proton and an oxygen of the nitro group leads to the loss of a hydroxyl radical $[M - 17]^+$. The fragmentation patterns of 46 NACs in EI ionization are summarized by Feltes et al.[62] The advantages of EI are the structural information obtained from fragmentation which, for example, usually allows the easy determination of the number of nitro groups present in a molecule, and the ability to use large spectrum libraries.

With chemical ionization, detection in negative ion mode is often used, since the formation of a radical anion is favored by the high electron affinity of NACs, especially in the case of polynitroaromatics. NCI allows more sensitive detection: a factor of 20 in single ion monitoring was reported for 2,6-DNT,[62] and more than two orders of magnitude for 1-nitropyrene and 3-nitrofluoranthene.[27] However, it yields much less fragmentation and is seldom used for quantitative analysis due to reproducibility problems.

In the authors' laboratory the following method is used in routine analysis of water samples with GC/MS, though the enrichment step with dichloromethane will be replaced by a SPE method in the near future. As internal standards, the deuterated analogs 2-nitrotoluene-*d*7 and 2,4-DNT-*d*3 are spiked into each sample prior to extraction. The 500 mL sample of water is extracted three times, each with 40 mL dichloromethane, and the combined extracts are concentrated in a rotary evaporator at 40 °C to about 1 mL and placed into 1.4 mL autosampler vials. If necessary for lower detection limits, the extract is further reduced in volume under a gentle stream of nitrogen. A 1 µL sample of the extract is injected on-column. A separation column with medium polarity is especially suitable since it allows a better separation of the DNT isomers than a nonpolar column. A typical separation is shown in Figure 3. For this separation DB™-1701 (or equivalent), 30 m × 0.25 mm, and 0.25 µm film thickness was used. The GC temperature was held at 40 °C for 1 min, then raised at 10 °C min^{-1} to 230 °C. The carrier gas was helium at 1.03 bar (15 psi) column head pressure, and detection done with electron ionization in SIM mode. The use of deuterated standards in such analyses is highly recommended to allow compensation of analyte losses during sample preparation and of changes in ionization efficiencies. For this purpose, some deuterated NACs are commercially available (e.g. from Promochem, Wesel, Germany).

Even higher selectivity and (due to the enhanced signal-to-noise ratio) sensitivity is possible with the use of MS^n methods, mostly employing a triple–quadrupole instrument (allowing MS/MS, tandem MS or MS^2) or an ion-trap detector, which is in principle able to provide even higher dimensions in MS detection. However, practical reasons limit the use mostly to MS/MS/MS (or MS^3). Recent examples of the use of tandem MS in the analysis of NACs describe the analysis of nitro-PAHs in air[63] and soil.[64] In the former application the best MS conditions were found to be selection of the molecule ion in the first stage of the MS instrument and subsequent reaction monitoring with detection of NO_2^- at m/z 46.

Figure 3 GC/MS chromatogram (EI, SIM) of a NAC mixture. Peak assignment: 1, nitrobenzene; 2, 2-nitrotoluene-*d*7; 3, 2-nitrotoluene; 4, 3-nitrotoluene; 5, 4-nitrotoluene; 6, 2,6-DNT; 7, 1,3-dinitrobenzene; 8, 2,5-DNT; 9, 2,3-DNT; 10, 2,4-DNT-*d*3; 11, 2,4-DNT; 12, 3,5-DNT; 13, 3,4-DNT.

A new, very interesting approach for the determination of NACs in soil samples was introduced by Williams and Pappas.[65] They used ultrahigh-speed GC on 0.5 m capillary columns and subsequent detection with a surface acoustic wave detector after thermodesorption of the analytes from soil for separation and detection of trinitrotoluene and DNT isomers in less than 2 min. The method was shown to be useful in the field for the approximate quantitation of those analytes, thus allowing a substantiated selection of samples for further investigations.

5.2 High-pressure Liquid Chromatography

HPLC is often the separation method of choice for the analysis of NACs. This applies especially for environmental analysis, since in many cases partly reduced metabolites, some of which are not amenable to GC analysis, have to be determined at the same time. Organic acids such as nitrotoluenesulfonic acids or nitrobenzoic acids also cannot be separated by GC without prior derivatization, and are mainly analyzed by HPLC. Another advantage of HPLC is the easier on-line coupling, with an enrichment step in comparison to GC, thus facilitating the set-up of totally automated analysis systems. A disadvantage of HPLC is the incompability of common solvents used in LLE with aqueous eluents in reversed-phase HPLC. In these cases a blow-down of the extractant and reconstitution in a suitable solvent is necessary, which might lead to the loss of more volatile analytes. Recent reviews were published on the HPLC analysis of explosives[66] and nitro-PAHs.[67]

Separation of NACs is usually performed with reversed phases and aqueous eluents. Methanol is the most widely used organic modifier, followed by acetonitrile. Depending on the analytes to be separated, isocratic elution may suffice or a gradient elution may be necessary. Some authors describe the isocratic elution with a ternary eluent,[68] although this is seldom used in routine analysis. C_{18} and C_8 stationary phases are mainly used. USEPA method 8030 demands the use of a CN column for confirmatory analysis since the elution order is completely different in comparison with the C_{18} primary column. The separation method used in the authors' laboratory is described here in more detail. It is superior to many of the published methods in terms of isomer separation and allows the analysis of at least 16 NACs in one chromatographic run. A typical chromatogram of a reference mixture is shown in Figure 4. For the separation a Nucleosil® 120 3-C_{18}, 250 × 3 mm column (Macherey-Nagel, Dueren, Germany) was used with the following gradient: methanol–water 35/65 (v/v), in 12 min to 45% water, isocratic for 28 min, in 10 min to 0% water (for column flushing), then re-equilibration for 15 min with the starting eluent. Flow was 0.35 mL min^{-1}, and detection was done with a DAD.

Figure 4 HPLC/DAD chromatogram of a NAC mixture, detection wavelength 230 nm. Peak assignment: 1, 2,6-diamino-4-nitrotoluene; 2, 2,4-diamino-6-nitrotoluene; 3, trinitrobenzylalcohol; 4, 1,3,5-trinitrobenzene; 5, 2-methyl-3-nitroaniline; 6, 4-methyl-3-nitroaniline; 7, 2-methyl-5-nitroaniline; 8, 1,3-dinitrobenzene; 9, trinitrotoluene; 10, 4-amino-2,6-DNT; 11, 2-amino-4,6-DNT; 12, 2,6-DNT; 13, 2,4-DNT; 14, 2-nitrotoluene; 15, 4-nitrotoluene; 16, 3-nitrotoluene.

A selective analysis of NACs is possible with the use of electron donor–acceptor complexes (EDA complexes) formation,[23,69] which allows separation according to the electron deficiency of the aromatic system. The stationary phase consists of clay conglomerates[23] or silica-based materials which are derivatized to yield electron-rich aromatic systems as end groups (naphthalene, *N*-methyl indole, anisole).[69]

The separation of neutral and acidic NACs in one chromatographic run was described by Caton and Griest[70] with a mixed-mode C_{18} anion exchanger column. A similar result can be achieved using acidified eluents[10] or ion-pairing chromatography,[71] since the retention of neutral NACs is hardly affected by pH or the presence of an ion-pairing reagent.

If more powerful separations are needed, the use of two-dimensional chromatography may drastically increase the peak capacity and separation power of the chromatographic system. To maximize these parameters the use of an orthogonal separation mechanism is ideal. Examples in the analysis of NACs are the selective analysis of nitro-PAHs in diesel exhaust particulates[72] and the analysis of water samples for nitroaromatic explosives.[73] In the latter case a safrol-modified silica provided the necessary selectivity difference from the primary C_{18} column.

A short overview of the most important HPLC detectors for NAC analysis is given in Table 6.

All NACs exhibit the more or less shifted benzene UV absorption bands. Therefore, a UV detector can be generally used, and is indeed by far the most widely applied detector.[74] Instead of using a confirmatory column, nowadays the use of a DAD is generally accepted, which allows compound verification via the on-line measurement of the compound's UV spectrum. The sensitivity of photometric detection is not very good,

Table 6 Comparison of detector types in HPLC

Detector	Instrument detection limits (pg)	Selectivity	Notes
UV/DAD	500–10 000	–	
Electrochemical	10–1000	o	Interferences by other reducible species, sensitivity increases with number of nitro groups
Fluorescence	10–500	+	Requires transformation, usually to aromatic amines, eventually subsequent derivatization
Chemiluminescence[a]	0.1–10	+	Requires transformation, usually to aromatic amines, and subsequent derivatization
MS, API, SIM (negative mode)	1–1000	++	Sensitivity increases with number of nitro groups
NMR	1 000 000	o	Only method for isomer identification

[a] Based on bis(trichlorophenyl)oxalate/hydrogen peroxide reaction with nitro PAHs.[67]
API, atmospheric pressure ionization; NMR, nuclear magnetic resonance.

therefore an enrichment step is always necessary for trace analysis.

Direct fluorescence detection of NACs is not possible because fluorescence is effectively quenched by the nitro group. To utilize such a detector therefore requires reduction to the corresponding amino compounds, some of which show intense native fluorescence (especially the amino-PAHs), but which can also easily be converted with standard derivatization reagents, e.g. fluorescamine, to yield highly fluorescing pyrrolinones.[75] The reduction can either be accomplished pre-column (mainly off-line) or post-column (mainly on-line) with a variety of reductants, including iron,[75] zinc[76] and hydrosulfide.[77] A disadvantage of the pre-column approach is the more demanding separation of the corresponding anilines in comparison with NACs, which mainly result from interactions with residual silanol groups. An especially interesting approach for post-column reduction of nitro-PAHs was recently described by Murayama and Dasgupta,[78] who used a coulometric detector for on-line reduction before subsequent fluorescent detection. By switching the coulometric detector on and off and subtracting both chromatograms they achieved an extraordinary selectivity. Another means to increase selectivity is a post-column reaction scheme which allows chemiluminescence detection.[76,77]

Electrochemical detection of NACs can principally be used in the reductive mode to yield the corresponding hydroxylamines or anilines (see section 4.2). In the review by Lloyd[66] on HPLC of explosives, different techniques for the reductive determination are thoroughly discussed, including hanging mercury drop electrodes and thin-layer electrodes. Cvacka et al.[67] give some examples of the use of amperometric detection in the reductive mode (potential in the range −500 to −650 mV) for environmental analysis of nitro-PAHs. However, a severe drawback of these methods is the interfering oxygen reduction, which leads to high background currents. Therefore a rigorous degassing of eluent and sample and the sole use of stainless-steel tubing is necessary. Still, in many routine applications oxygen interference cannot be avoided sufficiently. Thus the use of electrochemical detection in environmental analysis is more popular for NACs possessing other, oxidizable groups, such as aminonitro compounds or nitrophenols[79,80] which allow operation in the oxidative mode. The electrochemical detector shows a better selectivity (and often sensitivity) than a single-wavelength UV detector. However, use of an electrochemical detector requires much more operational efforts than does a UV detector. Besides, there are still problems with baseline stability in gradient elution, although the developments of the last few years are promising in that regard. An interesting approach was described by Krull and LaCourse,[81] who used a post-column photochemical reactor to cleave nitrite from the analytes, which was then detected in the oxidative mode.

In the past few years, high-performance liquid chromatography/mass spectrometry (HPLC/MS) has gained much attention for NAC analysis, as probably in all fields of HPLC analysis. The MS detection, particularly MS^n, allows in many cases unequivocal identification of analytes, even in difficult matrixes. Many commercialized interfaces have been used for the environmental analysis of NACs: thermospray,[82,83] particle beam,[84] electrospray ionization (ESI),[82,85] and atmospheric pressure chemical ionization (APCI).[82] From the authors' experience it is expected that ESI and APCI will become the standard interfaces over the next few years. NACs are mostly detected in the negative ion mode since the formation of radical anions

is favored by the electron-withdrawing nitro group. The sensitivity increases with the number of nitro groups and also for organic anions. Astratov et al.[82] compared the mass spectra of 26 NACs obtained with a thermospray, an APCI and an ESI interface, all operated in negative ion mode with methanol, water and formic acid as the mobile phase. In general, they observed the M^- or $[M-H]$ peak as the base peak with all interfaces. In a few cases, however, the use of APCI and ESI yielded clusters with methanol or formate as the base peak. The fragmentation increased from ESI over APCI to thermospray, reflecting the different thermal stresses prior to or during ionization. Astratov et al. emphasized that there is still a lot of variation in the mass spectra obtained, depending on the use of a specific instrument or interface. They did not provide data on the applied cone (also called fragmentation or capillary exit) voltage. The choice of the cone voltage is crucial for the fragmentation behavior of all NACs but in particular for acidic compounds such as nitrobenzoic acids and nitrotoluenesulfonic acids,[71] regardless of the interface type. With increasing cone voltage a higher degree of fragmentation is observed. The same behavior was found for polycarboxylates[86] and aromatic sulfonates.[87] Thus the cone voltage always has to be set at the same value to obtain reproducible mass spectra. On the other hand the possibility of in-source induced fragmentation offers the possibility of enhanced identification power even in single-quadrupole systems which are not capable of MS^n experiments. The ionization behavior of NACs (and other organic chemicals) in modern liquid chromatography coupled interfaces is not at all understood yet and requires a lot of further work.

Another hyphenated method which is increasingly being investigated is high-performance liquid chromatography/nuclear magnetic resonance (HPLC/NMR). Regarding the use for NACs, Preiss et al. did a number of initiative studies, mainly applied to the analysis of contaminated groundwater at ammunition waste sites.[88,89] This method is unique in its power to reveal the chemical structure of compounds, as even the distinction of positional isomers is possible. Therefore it is well suited for the most complex problems of structural analysis. However, despite advances in the last years, its lack of sensitivity is a major drawback in environmental analysis. Besides, it is very costly both in acquisition and operation and needs an experienced supervisor. Thus it is not expected to become a routine method in the analysis of NACs.

5.3 Capillary Electrophoresis and Related Techniques

During the last few years capillary electrophoresis (CE) has gained more and more importance in environmental analysis.[90] Among the capillary electroseparative techniques, CE, capillary electrochromatography (CEC) and especially micellar electrokinetic chromatography (MEKC) are of interest for the analysis of NACs. Instrumentation for these methods is similar: the main component is a fused silica capillary of a length between 20 and 100 cm and an internal diameter smaller than 100 μm. The capillary, which is filled with the separation electrolyte, is immersed at both ends into vials also filled with electrolyte. After the sample is injected in the capillary, a high voltage (up to 35 kV) is applied between two electrodes immersed into the vials. The temperature of the capillary has to be controlled and the hydrodynamic flow has to be minimized. Detection is usually carried out directly on a segment of the capillary (mostly by photometric or fluorimetric detection).

Whereas in CE only charged solutes can be analyzed because its separation principle is based on different electrophoretic mobilities of analytes, both CEC and MEKC make use of the distribution between two phases, enabling the separation of electrically neutral analytes.

CEC can be regarded as a hybrid technique between HPLC and CE. Using electro-osmotic flow, a mobile phase is driven through a stationary phase which is packed in the capillary. Bailey and Yan[91] used CEC to separate a series of 14 nitroaromatic and nitramine explosive compounds, achieving baseline resolution for all of the compounds in less than 7 min.

In MEKC, an ionic surfactant (usually sodium dodecyl sulfate, SDS) is added to a CE solution, forming micelles. The migration velocity of these micelles differs from that of the surrounding aqueous phase. The micelles are able to incorporate solutes and act as a pseudostationary phase. MEKC does not only extend the applicability of CE to neutral solutes, it also offers improvements in the separation of very complex mixtures. This is due to the numerous possibilities that are available for the manipulation of separation selectivity.

In comparison to classical chromatographic methods like GC and HPLC, capillary electroseparative techniques possess some unique advantages. High separation efficiencies (up to 300 000 plates per capillary) can be achieved easily under routine conditions, even for highly polar or thermal unstable substances, which are in general difficult to analyze. Sample volumes are very small, analysis time is short, and consumption of reagents and costs of columns are low. Moreover, minimal sample clean-up is necessary due to the exchange of the separation electrolyte in CE and MEKC after each run. Irreversible sorption of matrix constituents to the stationary phase cannot occur. Direct sample injection is often possible.

The analysis of trinitrotoluene and its transformation products in a variety of matrixes has been a popular subject of studies employing MEKC.[92,93] Mussenbrock and Kleiböhmer[94] optimized the separation

of 24 compounds of explosives via MEKC in less than 12 min, including all USEPA priority substances. Oehrle[95] used MEKC to analyze wastewater samples (called ''pink water'') from ammunition plants.

One major disadvantage of capillary electroseparative techniques is the relatively low LOD. Although featuring impressive mass sensitivity comparable to average GC systems, CE with its very small injection volumes of only a few nanoliters is usually not sensitive enough for environmental trace analysis when using photometric detection.

To enhance concentration sensitivity, three basic approaches are possible: increasing detection performance; off-line sample preconcentration; and on-line sample concentration.

The optical pathlength for detection can be increased using special detection cells such as z-shaped cells, multireflection cells, rectangular cells and bubble cells. The use of these cells may decrease separation efficiency, however.

For the analysis of NACs with their well-defined redox behavior, electrochemical detection can be useful. Hilmi et al.[96] presented an off-column amperometric cell for the determination of explosives by MEKC. In comparison to photometric detection, a ten-fold improvement of detection limit was achieved for most of the explosives tested in this study. The results were in good agreement with those obtained by the liquid chromatographic method recommended by the USEPA.

Thermal lens detection can also be used as alternative detection technique. Employing MEKC for the separation of nitrophenol pesticides, Seidel et al.[97] attained 1–2 orders of magnitude lower detection limits with thermal lens detection than with conventional photometric detection. Another promising effort to enhance sensitivity as well as selectivity is coupling of CE with MS.[98]

Using off-line sample preconcentration, CE can be employed for the analysis of nitroaromatics in water at ppb levels. Most SPE techniques can be transferred to CE. Rodriguez et al.[99] used cross-linked polystyrene for off-line concentration of nitro- and chlorophenols from water before separation with CE. Kaniansky et al.[100] used preparative capillary isotachophoresis (ITP) as a sample pretreatment technique for the analysis of nitrophenols. The following capillary zone electrophoresis (CZE) separation resulted in limits of detection of 2–8 ppb.

Furthermore, capillary electroseparative techniques offer the possibility of on-line concentration techniques that are not applicable in HPLC. One of them is sample stacking, which was initially developed for CZE. A large sample volume is injected. Differences in the effective migration mobilities of the solutes, caused by differences in the electric conductivity of bordering zones, result in focusing of the analytes in a narrow zone. This mechanism is also suitable for the on-line concentration of charged solutes in MEKC. With some modifications it can also be used for the concentration of electrically neutral species in MEKC, as the solutes exhibit an effective migration mobility during the stacking process, due to interaction with the pseudostationary phase.

In summary, capillary electroseparative techniques possess a high potential in this field. In some cases, they already offer a real alternative to GC and HPLC.

5.4 Thin-layer Chromatography

The use of TLC for the environmental analysis of NACs offers some significant advantages. Costs are low and analysis time is short, making this method ideal for screening purposes. Thermal degradation of analytes is insignificant. Moreover, TLC often does not require any sample clean-up. When analyzing soil samples in some cases it is necessary to use size-exclusion chromatography (SEC) to remove large amounts of humic acids.[101]

Due to the relatively poor separation efficiency of TLC, the method is not sufficient for certain identification of analytes. Two-dimensional TLC can improve separation significantly, employing binary as well as ternary mixtures of solvents.[41,102]

Automated multiple development high-performance TLC with a commercially available instrument was also successfully applied for the analysis of nitroaromatics and other explosives.[101] The development of the plate was done employing a stepwise gradient (25 steps) of the solvent, leading to a run time of about 4.5 h. Detection was performed with UV scanning. Detection limits ranged from 5 to 20 ng.

TLC employing different stationary phases was also used for the analysis of nitro-PAHs in environmental samples.[103]

Kessel and Hauck[104] developed a TLC method for qualitative screening and quantitative analysis of trinitrotoluene and its main degradation products in water samples after enrichment using SPE.

6 OUTLOOK

In general, the trend in environmental analysis of NACs is determined by advances in extraction, separation and detection methods. As an example it is to be expected that SFE and ASE, due to their ease of use, good extraction efficiencies and automatization possibilities, will become routine methods for the investigation of soil and particulate samples for NACs of all kinds. Separation methods will move to miniaturized systems. With the advent of more and more sensitive detectors,

the use of electrophoretic techniques will increase since they allow the most efficient separations of the whole range of NACs, from rather nonpolar compounds like nitro-PAHs (e.g. with CEC) to nitrosubstituted organic acids such as nitrosulfonic acids. The latter are increasingly recognized as pollutants of concern since their polarity allows fast movement in aqueous systems and penetration in drinking water reservoirs. The importance of oxidized metabolites of nitroaromatic explosives is also underestimated so far, which shows that despite numerous studies we still do not have a complete picture of the transformation processes for NACs in soil and water systems. Besides, nitration processes in the atmosphere are still not well understood. Atmospheric chemistry studies are extremely demanding in terms of analytical methods, and it can be expected that nitration will prove to be of more general importance for the formation of NACs than is known today. Regarding detection, the fast developments in MS are especially promising, both in terms of selectivity (enhancing the reliability of data) and sensitivity. For all ionization methods except EI there is still the need for a better understanding of the underlying mechanisms, thus allowing a better interpretation and prediction of mass spectra. The reproducibility of measurements has to be improved, since quantitation power is still limited. NMR methods may complement MS detection for identification of unknowns if they become easier to handle and cheaper to obtain. However, ECD in GC and a DAD in HPLC will remain the workhorses for NAC analysis in routine laboratories, at least for a number of years.

More sophisticated analytical methods allow the detection of lower and lower quantities of NACs, even in complex environmental matrixes. But to derive reliable information on environmental systems still requires more efforts in quality assurance of ultra-trace analyses. One way of providing unbiased data is the use of in situ methods, which will become more important, especially for the surveillance of point sources to aqueous systems. They already allow fast measurements with high temporal and spatial resolution without the problems involved with sampling and storage. Nowadays detection limits and stability of the systems are often not satisfying, but it is expected that both will improve over the next few years.

Nuclear magnetic resonance (NMR) technology is based on discoveries made in 1946, which have provided the basis for many applications in chemical identification, characterization, and imaging. The earliest use was for NMR spectroscopic studies of the molecular distribution of hydrogen, the nucleus detected by NMR with the greatest sensitivity. The use of NMR imaging was first explored in early 1970s, using fruit and vegetable specimens which provided good models for engineering. These early experiments clearly demonstrated the potential utility of NMR for nondestructive visualization of the internal components of intact specimens. Nuclei which can be detected and studied by NMR include those with unpaired electrons, such as ^{1}H, ^{2}H, ^{31}P, ^{14}N, ^{15}N, ^{17}O, ^{19}F, ^{27}Al, ^{23}Na and ^{39}K. Contemporary NMR units used for either imaging or spectroscopy have three major components: a large magnet, a radiofrequency (rf) coil, and a computer-driven console to control the pulse sequence and collect data. Samples are placed into the center of the magnet, allowing nuclei to become aligned either parallel or antiparallel to the magnetic field while precessing at a defined frequency which is proportional to the magnetic field strength. The nuclear precession is then realigned to a temporary magnetic field which is perpendicular to the primary magnetic field and is induced by the rf coil. Finally the rf coil is turned off, allowing spins to realign with the primary magnetic field and give off energy which is detected as an alternating current in the process. In NMR spectroscopic experiments, the molecular environment of each nucleus induces slight alterations in the magnetic field, which are detected as slight changes in the frequency of precession. This information is used to create spectra showing details of the molecular environment of the nuclei being detected, and information describing the structure of the molecule. With imaging experiments, electromagnetic coils are placed in the bore of the magnet, to create linearly defined alterations in the magnetic field. As with spectroscopic experiments, the specimen is placed in the center of the stationary magnet. Nuclei are realigned by pulses from an rf coil, and the energy given off is detected as an alternating current. With imaging, changes in the frequency of precession provide information describing the spatial location of the specimen within the bore, and allow images of the specimen volume to be acquired without disruption to the specimen. Use of electromagnets which create a linear magnetic field allows the precise position of the specimen and its morphology to be determined. Contrast within the images is determined both by the content of detected nuclei (usually ^{1}H within water), and by the interactions between nuclei and their surroundings. The advantage of analysis by NMR spectroscopy and imaging is that the samples can be studied without disruption to the specimen. Chemical analysis can even be done in vivo or in an undisturbed setting. Similarly, imaging can be done on live, intact specimens, the only requirement being that they remain immobile for some period of time. The limitation of these techniques is that only specific nuclei can be detected, with most imaging experiments primarily limited to water distribution and binding. Specimens must be sufficiently small to fit within the bore of the stationary magnet. The magnet bore size may range from a few millimeters for some spectroscopic experiments to up 100 cm with some imaging units. Additionally, the technique is relatively insensitive compared with other analytical techniques such as immunoassays or fluorescent assays. Nevertheless, NMR spectroscopy and imaging provide a unique and powerful set of tools for environmental assessment. Applications include examination of humic substances in soil, soil chemistry, chemistry of surface waters, aluminum chemistry in situ, pesticide fate when introduced into the environment, water uptake and translocation by plants, and structural studies of living specimens such as plant roots within a soil volume. New applications are constantly

appearing as magnet technology improves, new pulse sequences are developed, and coil design progresses.

1 INTRODUCTION

1.1 History and Background

NMR technology is based on discoveries made in 1946 by two groups of researchers, headed by Felix Bloch and Edward Purcell respectively. Its earliest use was in NMR spectroscopic studies of the molecular distribution of hydrogen, the nucleus detected by NMR with the greatest sensitivity. Today, similar spectroscopic experiments provide detailed information on molecular structure, and are used extensively in chemical analysis of many types of molecules. Many texts are available describing applications of NMR in determining molecular structure.[1,2]

The use of NMR for imaging was first explored in the early 1970s, using fruit and vegetable specimens which provided good models for engineering.[3] These early experiments clearly demonstrated the potential utility of NMR for nondestructive visualization of the internal components of intact specimens.

1.1.1 Introductory Theory

Nuclei which can potentially be studied with NMR are those with unpaired electrons. These include ^{1}H, ^{2}H, ^{31}P, ^{14}N, ^{15}N, ^{17}O, ^{19}F, ^{27}Al, ^{23}Na, and ^{39}K. Of these, ^{1}H can be detected with the greatest sensitivity. The high natural abundance of this nucleus in the water within both soil and biological tissue (such as plant roots), combined with its high detectability, makes this the most commonly used nucleus for NMR imaging and spectroscopic studies.[2]

There are three major components to NMR instruments: a large magnet, an rf coil, and a computer-driven console to control the pulse sequence and to collect and process received signals. Magnets used in contemporary spectroscopic and imaging units are usually static, superconducting magnets. They create a magnetic field which is parallel with the center bore of the magnet.

Another fundamental piece of hardware required for NMR imaging experiments is the rf coil which is placed either around or adjacent to the specimen. This is tuned to a frequency specific to the field strength of the magnet and the nucleus to be detected. It is also used to receive the alternating current generated by manipulating the nuclear spins within the bore of the magnet.

In practice, the sample is placed inside or adjacent to an rf coil. The specimen and the rf coil are then positioned in the center of the bore of the magnet, where the spins align themselves either parallel or antiparallel to the primary magnetic field. The distribution of alignments depends on the magnetic field strength and the identity of the nucleus. Since the detection of NMR signals depends on relatively small differences between the number of nuclei in parallel or antiparallel alignments, NMR is a rather insensitive technique compared with many others such as chemical or radioisotopic assays.

Magnetic resonance imaging (MRI) units are also composed of several computers linked by a communications network. The computers control all aspects of image acquisition and processing. The pulse sequences used to generate the images are stored in the main computers, and these control gradient generation, as well as controlling the rf coils needed for flipping the nuclei to be detected into defined angles of orientation and detecting the alternating current generated with each pulse. A substantial amount of memory is necessary to store the software required to run the machine, and to acquire and process images. Generally a minimum of 1 GB is needed for the scanner itself. Additional computers for off-line image reconstruction, processing and analysis are also desirable to maximize the time the scanner can be used for image acquisition.

The final component is the library of software necessary to run the gradients, power the rf coil, detect and amplify the alternating current received from the sample, and process the detected signal into an image using multiple Fourier transformations. Within the medical community new pulse sequences are continually being developed, either for specific diagnostic applications or to decrease the time necessary to acquire an image. Many of these have shown promise for enhancing capabilities for environmental monitoring.

NMR experiments can be viewed from the classical perspective, where the nuclear magnetism is derived from the spinning of the nucleus. The precessing motion of the nuclear magnetic moment within the externally applied magnetic field (the superconducting magnet) is described by the Larmor equation, a relationship which is fundamental to all NMR experiments. This relationship can be described as shown in Equation (1)

$$w = \gamma B_0 \tag{1}$$

where w is the frequency which with the nucleus can be considered to precess, γ is the gyromagnetic ratio for the nucleus being considered and is unique for each nucleus, and B_0 is the strength of the magnetic field.

Following placement in the magnet, the rf coil is pulsed in a prescribed manner at the frequency of precession of the nucleus of interest. This frequency is defined by the Larmor equation, and is directly proportional to the field strength. For example, at 2 T ^{1}H nuclei precess at 85 MHz, while at 7 T the frequency of precession is

300 MHz. The rf pulse creates a magnetic field, designated B_1, which is perpendicular to the static magnetic field created by the superconducting magnet. This causes the net magnetization of the spins to ''tip sideways'', with the degree of tipping depending on the strength and duration of the applied rf pulse. When the rf radiation is turned off, the spins realign with the static magnetic field. During realignment, energy is given off, which is detected by the rf coil as an alternating current. These detected signals are then amplified, filtered, and sent to the computer for digitization, recording, and processing. The process of exciting the nuclei by application of an external rf pulse, realignment, and signal collection is repeated many times for acquisition of an image as well as for most spectra.

For NMR spectroscopic experiments, slight variations in the frequency of precession of individual nuclei are created by interactions with the local environment, creating slight localized changes in the magnetic field, for example patterns of binding or paramagnetic interactions. Spectroscopic experiments, therefore, often provide detailed information describing the molecular environment of the nuclei of interest. There is no information regarding spatial localization of the nuclei in traditional NMR spectroscopy.

MRI is similarly based on the Larmor equation. It capitalizes on the frequency of precession being dependent on the specimen position within the magnet bore. Electromagnetic gradients within the bore of the superconducting magnet create linear, defined increases and decreases in the static magnet field, depending on the direction and distance down the bore from the magnetic field center. If we again consider the Larmor equation, the addition of magnetic field gradients gives the relationship shown in Equation (2)

$$w = \gamma(B_0 + rG_r) \tag{2}$$

wherein r is the position along the axis of the gradient G_r. At the isocenter, or the center position of the gradients, the magnetic field is equal to B_0. The gradient strength increases or decreases linearly from the center position.

1.1.2 Fundamental Parameters

There are three fundamental additional parameters inherent in NMR studies: spin–lattice relaxation time (T_1), spin–spin relaxation time (T_2), and diffusion. In addition, the number of detectable spins plays an important role in the detected signal intensity. Spin–lattice relaxation is a measure of time required for the spin population to return to equilibrium following excitation by the rf pulse. The spin system transfers its energy to its surroundings, termed the lattice, as a result of interactions with other local, fluctuating magnetic fields. The spins gain magnetization in the longitudinal, static orientation, with reorientation defined as an exponential gain. Spin–lattice relaxation time is described by the exponential function in Equation (3)

$$M_x(t) = M_0(1 - e^{-t/T_1}) \tag{3}$$

where $M_x(t)$ is the magnetization in the x plane at time t and M_0 is the initial magnetization. Spin–spin relaxation is an exponential decay process, describing loss of magnetization in the transverse plane B_1 following the rf pulse. Generally, both T_1 and T_2 decrease as water becomes more tightly bound to surrounding substrates and less mobile.

Using imaging experiments, early workers demonstrated that plant roots could be visualized in a variety of fields.[4] The presence of paramagnetic ions frequently found in soils such as Fe^{2+}, Fe^{3+}, Mn^{2+}, and Cu^{2+} shortens relaxation times, with the dominant effect being on T_1 at low concentrations, and increasing in effect on T_2 with concentration. When there are sufficiently high concentrations, especially of particulate iron, the relaxation times may be shortened to such an extent that either the image becomes distorted or there is a localized loss of signal in the area near the paramagnetic or ferromagnetic ions. Relaxation rates can therefore give information not only on water binding properties, but also provide indirect information about the chemical environment of the molecules of interest. For example, the measured T_1 for water in sand can range from 565 ms to 1465 ms, although all sand samples contained 25% w/w water and were of about the same particle size. The differences in relaxation time were due primarily to varied iron contents.[5]

In NMR images, contrast between different regions of a volume being imaged, between a root and the surrounding soil for example, depends entirely upon the inherent properties of the specimen and upon the choice of protocol used for image acquisition.[5,6] Image or spectroscopic acquisition approaches have been developed which enhance differences in T_1, T_2, water distribution, diffusion, and/or flow. Most often, it is a combination of these factors which allows the investigator to distinguish specific features of the specimen under study.

1.1.3 Resolution

NMR spectroscopic signals from molecules in solution have a characteristic lineshape, determined by the nuclear magnetic properties, resonance frequency, and spin–spin relaxation times. The natural linewidth at half-height ($v_{1/2}$) can be described by Equation (4)

$$\frac{1}{T_2} = \pi \Delta v_{1/2} \tag{4}$$

In general, signals or linewidths broaden as molecules become increasingly immobilized and T_2 decreases.

Therefore, spectra of molecules in metabolites and in extracts frequently have narrower linewidths than spectra of molecules in living tissue or in macromolecules (such as polyphosphates in fungal vacuoles or membrane phospholipids). Generally, as lines broaden they become less detectable or appear as broad lines underlying the signal of other molecules. Magnetic field homogeneity is a critical feature in NMR studies as resonance frequency is determined by magnetic field strength. If the magnetic field is not homogeneous in a spectroscopic study, significant line-broadening can occur, reducing the detectability of nuclei of interest and causing overlap of adjacent peaks. Nuclear magnetic imaging experiments also rely on a homogeneous magnetic field created by the static superconducting magnet. Without this static homogeneous magnetic field, magnetic field gradients created by the electromagnets may not provide the defined, linear magnetic field upon which good spatial resolution is dependent.[2]

Resolution in MRI refers to the digital resolution and is calculated by the field of view size divided by the number of pixels used to create the image. For example, an image of an apple might have a field of view of 100 mm, divided by 256 pixels, thus giving a resolution of 0.39 mm, the measurement on each side of each pixel. Images are acquired from three-dimensional (3-D) specimens, creating a two-dimensional (2-D) image from something which has volume. Typically, in a single slice plant imaging experiment, a slice might be 1 mm thick. Therefore, in an MRI experiment, the term voxel is used to denote the 3-D properties of the specimen. In the apple example, therefore, a voxel would have dimensions of 0.39 mm $\times$ 0.39 mm $\times$ 1 mm, or a volume of 0.152 mm^3.

Resolution considerations also usually dictate the choice of imaging equipment. Generally large bore scanners, as would be used in clinical applications, provide resolutions of 0.9 mm or more with a slice thickness of several millimeters. While these resolutions are appropriate for large specimens, generally environmentally relevant samples such as fine roots of plants are of a much smaller diameter and would likely not be detected under such imaging conditions. In contrast, if one is interested in the water distribution throughout a large specimen such as a mature taproot, such equipment might be most appropriate.

An additional consideration with respect to resolution is the process of diffusion, whereby nuclei (i.e. water for most imaging experiments) physically move between voxels during the period of image acquisition. This movement causes loss of signal as the water moves from voxel to voxel, changing precessional frequency as it experiences slight changes in magnetic field strength. This sets the theoretical limit of in-plane resolution to about 1 μm, based on diffusion losses in signal detection.[7] With recent developments in rf coils, the practical resolution in certain cases is approaching this theoretical limit, but generally resolution this fine also dictates a need for small specimen sizes.

1.2 Limitations

There are several limitations to the use of MRI in the study of environmental samples. These include the following: the subject for study must generally be smaller than 30 cm in diameter (to fit into the bore of a high-resolution imaging magnet); the specimen must be removed from the study site and brought to the lab for study since it must be placed within the magnet bore; and acquisition of a high-resolution spectrum may take several hours. New pulse sequences (the protocols used for acquiring images and spectra) are continually under development for medical applications, and many focus on shortening the time required to complete a study, which may reduce the time limitation. Many of these new pulse sequences show promise for plant, root, and soil studies. Several previously published reviews summarize applications for MRI in the study of plant physiological processes.[5,8]

One of the primary disadvantages of NMR is the inherent lack of sensitivity, which can be expressed as a signal-to-noise ratio (S/N) between spectral lines and the background signal (in spectroscopic experiments) or between the signal detected in each pixel and the background signal (in imaging experiments). The S/N is dependent on a wide range of factors including:

(1) relative sensitivity of the specific nucleus;
(2) the volume of the specimen or sample contributing to each signal;
(3) magnetic field strength;
(4) the design and construction of the rf coil;
(5) the number of times each pulse is repeated and data collected;
(6) line-width of the detected signal;
(7) relaxation times and their relationship to the chosen pulse sequence and data acquisition parameters;
(8) concentration of the specific detectable nuclei (i.e. specific isotopes) present in the sample or specimen.[2]

Generally the minimum concentration required for a specific molecule under study to be detected is 0.2 mM, although experiments can be designed for detection of molecules both above and below this concentration.

There is one fundamental difference between NMR spectroscopic and imaging experiments when determining sensitivity. If we consider a specimen with a volume of 5 mL, when a spectroscopic experiment is performed the signal is acquired from the entire 5 mL volume and is used to produce the resultant spectra. In imaging, however,

spatial encoding digitally separates the specimen into many voxels, each of which is probed individually and contributes its own signal. Many 3-D image sets are comprised of 128 ''slices'', with each slice arranged in 256×256 pixels. The entire volume is thus divided into 838 8608 voxels. In imaging, therefore, the 5 mL volume is divided into 838 8608 voxels, each with a volume of 0.0006 μL, which is many orders of magnitude less than the volume providing the signal in a spectroscopic experiment. As the signal detected is proportional to the number of nuclei, the signal detected from a single voxel is far less than the signal detected without spatial encoding. For this reason, although many other nuclei can be probed with NMR spectroscopy, MRI is generally restricted to nuclei such as ^{1}H, which are most readily detected and are highly abundant.

1.3 Potential Applications

Based on its versatility and ability to analyze relatively unprocessed samples, there are numerous applications for NMR techniques in environmental analysis. NMR spectroscopy is often used for the chemical analysis of environmental samples, either directly showing the chemical structure of compounds or through isotopic labelling techniques using NMR-detectable nuclei to show changes in the chemical structure of compounds of interest. Materials studied cover a wide range, including lignin from plants, the fate of pesticides in the environment, phosphorus metabolism in plants, carbon chemistry both in vivo and during decomposition in the environment (root decomposition in soil for example), and speciation of aluminum in biological material as well as in solution (surface waters, for example). Field applications have included the construction of a mobile field unit for the measurement of soil moisture (as described in section 2.2), as well as the study of water content and potential in soil samples. Several texts describe the range of NMR spectroscopic applications to environmental analysis.[9–12]

NMR imaging provides spatial information but lacks the sensitivity required for chemical analysis for most detectable nuclei. This technique has found wide acceptance as a diagnostic for human health, and use for environmental monitoring has been strengthened by developments within the medical community. Applications include the imaging of soil, providing some of the first views of soil properties and biology in undisturbed samples. MRI provides an alternative technique to the traditional study of soil which depends on destructive sampling (i.e. removal of plants from the soil volume or disruption of a sample soil core). The strength of the technique is in its ability to nondestructively show root and water distribution within a soil column, either within a core of field soil or a potting container. MRI has also proven extremely valuable in the study of intact, living biological specimens, including animal models for toxicological studies, plant structure and anatomy, water transport and distribution through plant roots, stems, and leaves, and rooting architecture and function.

2 ENVIRONMENTAL APPLICATIONS

2.1 Magnetic Resonance Imaging of Soil

The study of plants in soil has historically presented significant challenges to researchers interested in investigating undisturbed or intact systems. The inherently opaque nature of soil makes direct study of roots or of water distribution within soil difficult without using techniques for remote sensing, such as mini-rhizotrons, X-ray diffraction, computed tomography, γ-ray attenuation, or MRI.[13,14] The researcher is physically separated from the specimens, such as plant roots or water distributed throughout a volume of soil, and disruption of the soil volume destroys the integrity and geometry of the system.

Soil can present many challenges to MRI and spectroscopic experiments, owing to the inherent heterogeneity of soils. Early in MRI research, it was demonstrated that MRI techniques have the potential for nondestructively observing the spatial distribution of water and large roots in soil.[4] In an extensive examination of the MRI properties of soil, plant roots were imaged when potted into 30 different agricultural and 8 artificial soils. Image quality and the ability to detect roots suffered significantly when the ferromagnetic particle content was greater than 4%. The presence of paramagnetic or ferromagnetic ions and particles within a soil volume creates localized alterations of the magnetic field within the soil volume, distorting the signal received and creating significant artifacts in the subsequent image. Below 4%, there was still significant variation in the suitability of a soil as a root imaging substrate.[15] This is especially important if the objective of the experiment is to make quantitative measurements of root volume, root area, water content, water distribution/flow/diffusion within the soil volume, or other similar measurements.

2.1.1 Experimental Design Considerations

There are several choices to be made when selecting an MRI unit, with a range of sizes and magnetic field strengths determining sensitivity and possible image resolution. The units commonly used for medical applications are constructed of a superconducting magnet with a field strength ranging from 0.5 T to 3 T (1 T or tesla = 10 000 gauss). The size, weight, cost, and technical

difficulties increase with magnetic field strength, however, making high-field magnets with bores large enough to image intact biological specimens or human patients generally impractical with current technology.

In contrast, MRI units that are primarily designed for research generally have magnets with a field strength from 2 T to 9 T. The size of the opening in the magnet for specimen position generally decreases with field strength, ranging from 30 cm to less than 1 cm, depending on the magnet design. For small-volume samples in which the highest resolution is desired, a small-bore, high-field magnet is usually most appropriate. If the specimen is large and the highest resolution may not be necessary, for example in the imaging of logs or large soil volumes, larger bore, lower field strength magnets are used.

2.1.2 Water Content and Distribution

Owing to its nondestructive and noninvasive attributes, water potential, content, and movement can be determined through NMR imaging and spectroscopic techniques. MRI has been demonstrated to give information on the pore structure and wettability of natural sandstone, providing visualization of wetting heterogeneities.[16] The T_1 relaxation time of water in natural sandstone was shown to increase significantly with silanization, changing the wettability of the surface from moderately hydrophilic to hydrophobic. Samples were infiltrated with water, then imaged. Subsequently, there have been other studies using MRI techniques to describe water distribution and flow through porous media such as sandstone, providing information describing the complicated flow and diffusion patterns.[17,18]

Similarly, the binding properties of water by fine sand as reflected by the relationship between relaxation time and water content have been studied. T_1 values increased from 472 ms when containing 5% water (w/w) to 1265 ms at 25% water. The increase in T_1 was linear between 5% and 20% with a slight reduction in slope between 20% and 25%. The water potential was measured as between 0.01 and 0 MPa, indicating lack of tight water binding by the sand grains.[5,19]

In addition to the study of soil/water interactions and the water content of soil, MRI provides the ability to study plant/soil interactions at a resolution not previously possible. In addition to spin–lattice relaxation time changes with water content, the detected signal intensity of water in sand increased linearly with water content with some pulse sequences complementing study by more traditional techniques such as neutron activation probes or soil moisture blocks. Studies of both the water content and distribution within the soil/sand matrix surrounding roots and visualization of the undisturbed root system can be achieved. The linear relationship between signal intensity from moist sand and water content allows direct measurement of the water content of sand by MRI when a standardized reference tube filled with copper sulfate solution is placed in the image field of view. The development of varied pulse sequences and the ability to control the environmental conditions within the magnet bore provide the possibility for study of patterns of water distribution and binding within sand (and the influence of roots of transpiring plants) as well as the architecture of roots in an undisturbed soil volume.

Experiments have been conducted to measure quantitative uptake of water from sand by plant roots. In these experiments, pine seedlings were planted into fine sand, watered to field capacity, and imaged repeatedly during a period of transpirational water uptake. Plants remained undisturbed within the bore of the magnet and continued to transpire under illumination from a fiber optic lamp placed into the magnet bore. Over time, regions of low detectable signal were observed to form around the roots which were shown to be regions from which water was withdrawn from the sand by the plants. The ''dark'' regions surrounding the roots were first observed around the top of the taproot and the fine roots. The margins were seen to expand over time, showing expansion of the root-associated water depletion zones as the plants continued to withdraw water from the sand through transpirational uptake.[5,19,20]

Water uptake by specific roots can be determined by MRI. Specific regions defined as containing pine seedling roots were imaged, and the areas of the water depletion zone surrounding each root were measured. The amount of water extracted from sand was measured by determining the volume of the water depletion zone by tracing the margins visualized in the images and determining the water content of the sand both within and outside the depletion zones. Comparative measures of water extraction for fine roots, woody lateral roots and the taproot of loblolly and red pine seedlings were calculated. It was found that the fine roots were very efficient at water extraction based on root weight and surface area. What was perhaps more surprising, however, was the formation of a water depletion zone surrounding the developing taproots.

In these experiments it is necessary to first calibrate a standard curve for detected signal intensity, and to include a reference material within each field of view. It is useful to include a glass tube filled with a mixture of water and $CuSO_4$ solution. The signal intensity of the reference tube and of specific regions of sand are measured from the acquired images. The ratio of these two signal intensities is then fitted to a predetermined regression equation, and the water content of the sand can then be estimated.

This method has provided some of the first views of water extraction by plant roots, and clear evidence that

the woody taproot of pines contributes to water uptake. There are some limitations to the method, however. The first is that image acquisition takes approximately 1 h, using a multislice technique wherein images of nonadjacent slices can be simultaneously imaged. For very rapidly transpiring plants, however, this may not be sufficient time for acquisition of high-quality images. A second limitation is that acquisition of a true 3-D volumetric image of the entire soil column and root system requires substantially more time – up to several hours in some cases. Again, if the subject of study is rapidly transpiring, the volume of the water depletion zone may change substantially during the period of image acquisition. The strength and power of the technique, however, generally outweights its limitations in that it provides definitive information showing the volume and location of the water depletion zone, its spatial relationship to the root system in situ, and water extracted by individual identified roots. A single container can also be repeatedly studied, showing changes in water distribution through time.

2.1.3 Root Distribution and Physiology

Another application is in the direct study of root geometry, architecture, growth, and turnover within the soil column. The nondestructive nature of MRI and NMR spectroscopy allows repeated study of a specific root system. When a root becomes nonfunctional with respect to water uptake, it becomes extremely difficult to distinguish it from the surrounding soil matrix, presumably because it has equilibrated in water content and binding with the soil around it. Images with contrasts primarily weighted by differences in T_1 show substantial differences with respect to signals detected between roots and water in the surrounding sand. Thus, root elongation, senescense, and replacement can be seen. This allows functional pine roots to be readily distinguished from nonfunctional roots, a critical distinction with regard to plant health, within an undisturbed soil volume (Figures 1 and 2).

The development of MRI protocols for the acquisition of truly 3-D image sets allows digital extraction of the root system from the soil column, without physical disturbance of the root system in soil. The digitally extracted root system can be measured for volume and surface area using software packages such as VoxelView (BioImage, Ames, Iowa). If appropriate markers are placed in the soil column, or are identified on the root system, image sets can even be registered with one another so more subtle changes can be studied by placing one digital root system alongside or within another. A root can be repeatedly imaged at multiple points in time, allowing quantitative analysis of growth, death, and replacement.

(a) (b)

Figure 1 3-D image acquired by MRI of a pine seedling root system. The plant was grown in a sand-filled container and watered routinely to field capacity. The image set was acquired with a spin–echo pulse sequence. The image set has been volume rendered to make the sand and water surrounding the root system transparent, allowing the intact root system to be viewed without removal from the container. Both images are of the same seedling: (a) seedling at approximately 6 weeks of age; (b) seedling at approximately 10 weeks of age.

Figure 2 Single slice image through a sand-filled container planted with a pine seedling. The view shows a cross-section through the taproot and bunches of fine roots within the soil volume. Slice thickness was approximately 1 mm. Seedling on left was approximately 6 weeks old. Seedling on right was approximately 20 weeks old.

Again, however, one of the present limitations of the technique is the time required for acquisition of a high-quality 3-D image set using the more common image acquisition approaches. A time requirement of 3–7 h is not uncommon for a single 3-D image, depending on the study requirements. As use of the equipment can be extremely costly, and plant study applications are often competing with studies which generate substantial funding (drug trials, for example, or clinical diagnoses from paying clients), this time requirement may become a serious limitation.

2.1.4 Future for Magnetic Resonance Imaging Study of Soil Systems

The technology is constantly changing, with new imaging protocols in development. In clinical research, it is to the diagnostician's benefit to decrease the time required for a clinical diagnosis so more patients can have access to the machine in a given period of time. These interests have caused the recent development of many new pulse sequences with a substantially shortened time requirement. While many are not applicable to plant root studies because of the S/N reduction (the smaller voxel size in most plant studies dictates less signal detected for each voxel) compared with medical applications, several hold promise for bringing MRI from the realm of casual interest to becoming a true research tool in the study of plant roots and below-ground processes. Unfortunately, the number of plant researchers who have access to such equipment is limited at present, but with time hopefully this will change.

2.2 Field Application of Nuclear Magnetic Resonance Spectroscopy for Soil Study

One unique application of NMR in environmental monitoring is the use of a mobile, low-magnetic-field-strength unit used in forestry and field settings to measure soil moisture. An NMR unit was designed to be pulled at relatively slow speeds behind a tractor, allowing relatively rapid measurement of surface soil water content over large areas. Field tests have been made at ground speeds from 0–17 km h^{-1}, with a correlation to water content measurements made gravimetrically estimated to be $r = 0.98$.[21]

As the emphasis in environmental monitoring expands to the examination of landscape-scale questions, development of methods to acquire environmentally relevant information at these scales becomes increasingly critical. In support of these studies, remote-sensing techniques (aerial photography and satellite imagery) have emerged as critical tools in the examination of environmental issues. Interpretation of these information sets, however, requires careful ground validation and supplemental testing of the land surface. The mobile NMR spectrometer was designed to characterize soil water content over large areas, to calibrate and verify remote sensor output. Accurate ground-truth information to verify interpretation of measurements made through remote sensing is critical to

accurate interpretation of remote sensor output. Water content, therefore, was determined in the field by measuring the strength of the ^{1}H NMR signal from water in the soil.

2.2.1 *Experimental Design Considerations and Limitations*

Construction of a unit designed for soil water measurements in a field setting requires a magnet to generate the static magnetic field required for resonance, an rf coil with tuning capacitor, and electronics to control the pulse sequence and data acquisition and processing. In addition, the unit must be sufficiently rugged to withstand movement across uneven terrain and exposure to the out-of-doors. In this design, an electromagnet rather than a superconducting magnet was used. The magnet and rf coil with tuning capacitor were designed to be mounted on the back of a tractor, with the electronics located in a weatherproof, air-conditioned steel enclosure mounted just behind the tractor cab. The magnet was approximately 60 cm long with a pole separation of 23 cm. It operated at a relatively low field strength of 700 G. The rf coil operated at a frequency of 3.0 MHz. Electrical power was supplied by a generator mounted on the front of the tractor. Electronics included rf pulse generators, amplifiers, signal processors, and the magnet power supply. The electrical requirements for magnet operation are determined by depth of measurement. Approximately 300 W of electrical power is required for a measurement depth of 51 mm, but approximately 500 W is required with the sensor in the flat configuration. The magnet was fabricated from 512 turns of 0.16-mm thick Al ribbon, bonded to a steel core and encased in a nonmagnetic stainless-steel housing for environmental protection.

Special consideration was needed in the design of the magnet and rf coil. In most laboratory applications, the sample is surrounded by the rf coil, and the assembly is placed in the center of a superconducting magnet. In this arrangement, the sample (the soil surface) was external to both the rf coil and the electromagnet. The size and location of the measurement region are determined by the placement and magnitude of the static magnetic field and the rf field. The poles of the electromagnet are positioned ahead of the measurement region, below the rf coil. As the unit moves across the landscape, nuclei become aligned in the static magnetic field prior to reorientation by the rf field pulse. In this arrangement, the time for the nuclei to align with the static magnetic field is determined by the magnet extension in front of the rf coils, and the transport speed.

In addition to the design constraints, the unit must be constructed for the soil to contact or nearly contact the surface of the unit. The sensor unit can be designed with two different configurations, depending on the application. In the flat arrangement, the sensor rides directly on the soil surface. This provides a stationary arrangement, most suited to flat terrain. In the extended configuration, extended magnetic pole pieces can be positioned into two 10-cm deep furrows. The poles can be adjusted to different soil depths, and NMR measurements of soil water content have been shown to be highly correlated with gravimetrically measured soil water contents at 38, 51, and 64 mm below the soil surface.

The unit was field tested by examining the soil water content of three clay samples (montmorillonite, kaolinite, and illite) and sandy loams with varied levels of organic matter. The soil water contents were measured in the laboratory using standard gravimetric techniques (oven drying and weighing), for comparison with NMR determined measurements.

2.2.2 *Software Considerations*

A spin–echo pulse sequence was used to measure soil water content, with the amplitude of the spin–echo a measure of the water content. In this sequence, spins are initially aligned parallel or antiparallel with the static magnetic field created by the electromagnet. The rf coil is pulsed, causing spins to realign to a 90° orientation relative to the static field. Spins are pulsed a second time, creating a 180° flip of the spins. The rf coil is then turned off, and the spins are allowed to realign with the primary, static field. Use of the second 180° pulse creates the formation of a signal "spin–echo", detectable by the rf coil. The rf pulse sequence is completed in 40 μs, and it is repeated 10 times per second, making the pulse sequence repetition time 40 ms. Accumulated signals are acquired for 25.6 s, then averaged.

Spin–lattice and spin–spin relaxation times were determined for water in loamy fine sand (400 ms/40 ms and 200 ms/1 ms respectively) and silty clay (200 ms/5 ms and 130 ms/700 ms respectively). Relaxation times are a reflection of the degree of binding and interaction between water and the surrounding matrix, (soil particles in this case). For the signal detected to be proportional to the number of spins in the sample in NMR spectroscopic experiments (water content in soil in this case) the repetition times between rf pulses should be equal to at least four times T_1. Under most conditions, this constraint is met, so the detected signal in the array is proportional to the water content in soil with this choice of pulse sequence and application.

It should be noted, however, that both T_1 and T_2 values decrease with increasing field strength of the stationary magnet. In addition, the relaxation time for water in other soil types must be determined, since the binding potential of soil and the presence of paramagnetic or

ferromagnetic ions in the soil will greatly affect both spin–spin and spin–lattice relaxation times. Therefore, relaxation times should be determined for each apparatus and field application, and appropriate pulse sequence parameters established for water content determinations.

2.3 Aluminum in Surface Waters

Some forms of Al(III) have been demonstrated to exhibit toxic effects in aquatic and terrestrial ecosystems, affecting fish, plants, mammals, and other organisms, making aluminum study in environmental samples extremely important. Development of methods for the detection and measurement of aluminum is crucial to our understanding of Al(III) chemistry and toxicity in natural waters, soil solutions, and environmental samples. Traditional colorimetric assays, by their very nature, alter Al(III) solution chemistry, potentially biasing measurements. Chemical analysis by complex formation gives specific information on the complexed aluminum species, but may not provide information on other Al(III) forms present in the sample. Magnetic resonance spectroscopic techniques have been developed to measure unaltered Al(III) in aqueous solution, whether from soil, surface waters, environmental samples, or extracts, providing an important tool for the study of this complex, environmental toxicant.

^{27}Al NMR spectroscopy (spin 5/2, 100% natural abundance) allows study of the chemical characteristics of the sample without alteration of the inherent chemistry. In addition, as with NMR imaging, the analysis is nondestructive, allowing repeated examination of the sample as needs dictate.

2.3.1 Experimental Design Considerations and Limitations

While Al exists as the most abundant element in the Earth's crust, it usually occurs at dilute levels (in the order of 10^{-5}–10^{-6} M[9–12]) in areas of environmental interest such as lakes, rivers, streams, biological samples (fish, plants, etc.), and soil extracts. This is at least one order of magnitude below the sensitivity of most commercial NMR probes. In addition, most vendor-supplied NMR probes and sample tubes designed for multinuclear NMR contain appreciable amounts of Al, resulting in high background signals that mask the desired signals from natural samples.[22]

Techniques to circumvent interference from the probe background include:

(1) study of solutions with concentrations $> 10^{-3}$ M;
(2) filtering the broad background signal by increasing the preacquisition delay from 150–200 μs to few microseconds;
(3) use of a spin–echo pulse sequence to edit out the background; and
(4) use of difference spectra to digitally subtract the probe background.

Since samples of biological and environmental relevance generally have levels of Al in solution well below 10^{-3} M, studies at high concentrations are often impractical. Concentration of samples to improve sensitivity is also likely to alter the solution chemistry of Al, making this a less-than-desirable choice. Filtering and spin–echo methods can sometimes be effective, but fail when the background and resonance-of-interest have similar linewidths, and may potentially decrease the sensitivity of detection. In particular, broad resonance from Al(III) complexes with biologically important ligands (e.g. organic acids, phosphate, and hydroxy ligands) could go undetected. In difference spectroscopy, the low levels of detectable Al in natural samples make subtraction uncertain, resulting in incomplete background subtraction and ''baseline roll''.

To address these challenges and to produce a probe for NMR spectroscopy of Al in solution, a novel probe was designed and constructed to reduce probe background and maximize sensitivity for the detection of ^{27}Al in solution. The successful construction of such probes provides new tools for the study of Al(III) speciation in dilute, natural samples collected from the environment.[23,24]

2.3.2 Coil Design for Environmentally Relevant Measurements

A novel probe was designed and constructed for analysis of environmentally relevant concentrations of Al both in solution and in vivo. To minimize the detectable Al background signal from the probe itself, materials for construction were selected based on prior analysis by neutron activation analysis for Al content. Three primary components were constructed:

(1) a probe body constructed of polycarbonate replacing the aluminum components of the housing in commercial probes;
(2) a solenoid rf coil designed for increased sensitivity to ^{27}Al from the sample, tuned by inductive coupling of three separate copper rings rather than by a variable capacitor (which are usually constructed of either ceramic or sapphire, both of which contain detectable aluminum); and
(3) a sample holder specifically milled from Teflon® to fit into the rf coil support.

Two separate chambers were constructed, one for a reference solution (8×10^{-4} M $Al(OH)_4$, pH 13) and

one for the sample material, either in solution or as biological material. The magnet was a 7-T 89-mm wide-bore vertical magnet. The solenoid coil was assembled around a 3.6-cm-o.d. cylindrical Teflon® insert.

To construct the coil, a 3-cm × 11-cm sheet of 2-mil (50-μm) thick microwave substrate was etched to remove about two-thirds of the copper from one side of the strip, while leaving all the copper intact on the other side. The strip was soldered to form a coil sliding freely on the coil support. Two additional copper loops, each 1 mm wide, were placed on the coil form on either side of the main coil. One of these was attached to the coaxial cable to serve as an inductively coupled pickup coil. Tuning and matching were accomplished by adjusting the distances between the three coils on the coil support.

To additionally reduce pickup of aluminum signals from the instrument hardware, unshielded coaxial cables were used for connecting electronic components in the NMR probe, as aluminum braid is frequently used as rf shielding. To reduce background detection, the entire probe was wrapped in copper foil.

2.3.3 Pulse Sequence Design

The coil was tuned to 78.199 MHz at 22 °C, and operated without lock. The internal reference material was used to normalize the spectrum. Acquisitions generally included a 40-μs pulse, with a 348-ms recycle delay, a 51-μs readout delay, 8192 points, 11 764-Hz sweepwidth, and 10-Hz line broadening. The number of transients collected varied between samples, depending on aluminum concentration.[2]

2.3.4 Sensitivity Enhancement

The study of Al in natural samples, without alteration of the chemistry present at the time of study or sampling, requires sensitivity as well as specificity. NMR spectroscopy under specific conditions can provide the sensitivity needed for these kinds of studies. Several considerations need to be made to enhance detection. The first is that not all Al ligands are readily detectable. As a quadrupolar nucleus, ^{27}Al has an inherently broader line and shorter T_2 times than dipolar nuclei such as ^{1}H. The less symmetrical the Al-containing molecule, the broader the line and the less detectable the ligand. This property in itself provides information describing the molecular geometry, but also presents a challenge to detection. Therefore, molecules which are most likely to be detected at environmentally relevant concentrations are those which are symmetrical, such as $Al(OH)_4^-$ or $AlCl_3$.

A second consideration is that ^{27}Al gives a substantially less detectable signal than ^{1}H nuclei, a property linked to both the quadrupolar nature of the nucleus as well as the gyromagnetic ratios. Having more sample available for study is an asset, so use of a wide-bore magnet is extremely valuable in the NMR study of ^{27}Al. In previously reported studies, approximately 11 mL of solution was within the sample volume detectable by the solenoid rf coil. Construction of larger diameter sample containers, to be used at higher field strengths (also increasing detectable signal), would improve the detectability of ^{27}Al as a potential candidate for environmental NMR study.

2.4 Carbon in Soil – Nuclear Magnetic Resonance of Humic Materials

Humic substances are complex mixtures of organic acids found in soil sediments and in natural waters of the geosphere, and are derived mainly from the weathering and decomposition of plants. Humic material includes macromolecules that have ill-defined structures and are lacking in repeating units. This molecular heterogeneity and complexity has left open to debate many fundamental questions about the structural chemistry of humic substances. NMR spectroscopy has provided useful insights that broaden our understanding of the origins of humic substances, their influence in land and water management, and the fate of pollutants and contaminants.

Humic substances have been extracted and/or methylated and studied in deuterated solvents since the earliest continuous-wave ^{1}H and ^{13}C NMR studies of humic materials.[9] The first good Fourier transform ^{13}C NMR spectra showing detailed separation of aromatic and aliphatic resonances of dissolved humic and fulvic acids appeared in 1976.[9] Direct examination of humic substances in the solid state avoids structural changes due to solubilization, and the first solid-state cross-polarization magic angle spinning spectra of humic material appeared in 1980.[25–27] This is of particular benefit for NMR studies of the insoluble humin fraction. Complete references to early NMR work are found in reviews published in 1983[28] and in two books published in 1987.[10,29] Recent reviews have focused on new ^{15}N and ^{13}C NMR enrichment techniques to trace the reactivity of humic substances with regard to degradation and interaction with contaminants and pollutants.[30,31] The International Humic Substances Society has catalogued standard and reference fulvic and humic acids by ^{13}C and ^{1}H NMR spectroscopy.[32]

Traditionally, humic substances have been separated into humic acids (base-soluble fractions), fulvic acids (fractions soluble under all pH conditions) and humins (insoluble fractions). Precipitation of the humic acid fraction at acid conditions could hydrolyze phosphate esters. Thus, many researchers today prefer to use

the total extract of the geo-organic material instead of individual fractions, particularly when preparing samples for ^{31}P NMR. Removal of paramagnetic ions, e.g. reduction of Fe^{3+} and Mn^{2+} with dithionite[33] can lead to improved NMR spectra of humic substances, particularly for quantitative data[9,31,32] in both the solution and solid state. Removal of mineral matter with HF also improves the NMR spectra of organic matter in sediments and soils.[34]

^{13}C NMR spectra of humic substances show overlapping signals in four distinct chemical shift ranges: aliphatic carbon signals (0–50 ppm) from alkyl side chains in amino acids, lipids, and plant polymers; *O*-alkyl carbon signals (50–110 ppm) from plant carbohydrate and degradation products; aromatic carbons (100–160 ppm); and carbonyl carbon signals (170–200 ppm) from carboxylic acid and carboxamide groups.[29,35] ^{1}H NMR in the liquid state with poorly resolved envelopes in the alkyl (0–2.5 ppm), *O*-alkyl (3–4 ppm), and aromatic (6–8 ppm) region is by comparison much less widely used.[9,10] ^{31}P NMR of soils and sediments allow observation of the inorganic phosphate pool (P_i) and the organic phosphate pool (P_o) such as phosphate esters, pyrophosphates and phosphonates with their direct carbon–phosphorus bond.[36,37] ^{15}N NMR of soil humic acids incubated with ^{15}N-enriched nitrate showed signals from secondary amides, most likely from protein material.[38]

A brief survey of NMR applications to humic substances reveals recurring themes of comparisons of humic materials from differing geochemical sources, studies of the decomposition processes in humification, studies of binding to metal ions, studies of interactions with pollutants and contaminants, and studies of formation of adducts.[39] Thus, ^{13}C NMR reveals dissolved humic substances from seawater to be enriched in total carbon but depleted in saturated carbon relative to humic substances in river water. ^{31}P NMR reveals persistence of phosphate esters and phosphonates at various depths in marine sediments from pelagic, lower shelf, and continental shelf depositional environments.[40] Solid-state ^{13}C NMR yields the insight that vegetational background (peat bog, spruce, pine, and oak forests) has a significant influence on the chemical composition of the humus in the soil[41] and that carbohydrates decrease in relative concentration while paraffinic substances persist in the decomposition processes of mangrove leaves in a tropical estuary.[42] The solid-state ^{13}C NMR spectra of humic acid, fulvic acid, and humin fractions sum to give a composite spectrum virtually identical to that of whole soil, indicating that conventional humic material fractionation does not change the carbon content of different functional groups in soil.[43] Effects of land use are seen in ^{31}P NMR results, revealing a larger inorganic phosphate pool in grass and arable soils compared with spruce and deciduous forest soils.[44] Solid-state ^{13}C and ^{15}N NMR of ^{13}C- and ^{15}N-labeled decomposing ryegrass reveals the *O*-alkyl-C signal (probably from carbohydrates) and the ^{15}N signal (probably from ^{15}N-amides) decreased, while the alkyl- and methyl-C content of soil increased over time.[45,46]

2.5 Pesticide Monitoring In Vivo and In Soil

Dissolved geo-organic matter in lakes and rivers can increase the solubility of pesticides, fertilizers, pollutants, and contaminants and threaten the quality of water supplies. Insights into the interactions of these pollutants with humic materials are needed to understand the migration of these pollutants in the water table. Chemical binding of pollutants to humic substances might decrease the risk of further transport. Irreversible binding, e.g. formation of stable chemical adducts, might be a natural detoxification process. Thus, while much early work centered on assessing the stereochemistry of pesticides themselves and some metabolites,[12] current approaches focus on the combination of labeling and NMR strategies to investigate specific molecular interactions. Anderson has reviewed ^{1}H and ^{19}F solution NMR of pesticide intermolecular interactions,[47] discussing solution complexes of the herbicide atrazine, and the pesticide 1,1,1-trichloro-2,2-bis[*p*-chlorophenyl]-ethane (DDT), DDT interactions with serum albumin and with phospholipid membranes, and fluoroaromatic–humic acid molecular interactions. Bortiatynski et al.[48] have presented ^{13}C labeling in combination with T_1 relaxation time measurements to study the binding of chlorophenols to humic acid. A covalent complex forms in the presence of an oxidoreductive enzyme. Herbert and Bertsch have used ^{2}D and ^{19}F NMR to study the interaction of nonionic organic contaminants with a Lakeland soil.[49]

The ability of the inductively coupled plasma-atomic (or optical) emission spectroscopy (ICP-AES (or OES))) system to perform multielement trace metal analysis of environmental samples provided commercial laboratories with the needed incentive to enter into the business of efficient trace metal analysis. Previously, trace metals were typically analyzed using colorimetric techniques, which were both cumbersome and subject to interferences, or flame atomic absorption techniques, which, although almost interference free, were labor intensive owing to their one-element-at-a-time analytical mode. Even the furnace atomic absorption technique, for years the standard bearer of low-level trace metal analysis, is giving way to axial and radial viewed ICP-AES techniques. Now, ICP-AES has become an affordable and well-established multielement analytical method.

Taking the USEPA (United States Environmental Protection Agency) SW-846 solid waste analysis manual as an example, this article reviews the methods used for the preparation of samples and the ICP-AES analysis of the prepared samples for trace metals in environmental matrices. This review includes recent developments in front-end improvements in ICP-AES and a detailed overview of the quality control (QC) requirements for environmental ICP-AES analysis.

1 INTRODUCTION

Philosophers tell us that when we look back at our life's journey, the events that we viewed as a series of random unconnected acts when we were living them became instead a path that has cohesion and rationality. Such has been the history of ICP-AES for environmental analysis. These authors remember the pre-ICP (inductively coupled plasma) days when to perform multielement analysis flame atomic absorption spectrometers were relied upon, which required the use of a different hollow cathode lamp and in some cases a different burner head for the analysis of each element. In the ICP-AES approach, the energy to ICP torch is induced by radio frequency (RF) energy through the three-ring, water-cooled load coil surrounding the three concentric quartz tube torches. Plasma is initiated by introducing a highly energetic electron surge by a Tesla discharge or piezoelectric solid-state transducer. The resulting ions and electrons interact with the oscillating magnetic field produced by the load coil, promoting further ionization of argon gas atoms via collisional interactions, thereby creating sustainable plasma rich with Ar^0, Ar^+, and free electrons. The electron temperature in the plasma can reach 8000–10 000 K. Thus, the ICP facilitates sufficient energy to the aerosolized sample stream to vaporize ($MX_{(g)} \rightarrow M_{(g)} + X_{(g)}$) and to atomize analyte elements. In the hot zone of the plasma, electrons in analyte atoms are promoted to higher energy levels (excitation), and, at appropriate plasma conditions, some of these atoms are ionized to form ions ($M^+_{(g)}$). Excited analyte atoms later

Figure 1 Block diagram for inductively coupled plasma atomic emission spectroscopy (ICP-AES) system.

reach the ground state, emitting characteristic energy at appropriate wavelengths. These wavelengths are unique to each analyte atom, and they can be used to identify unknown elements, while intensities of these emission signals are directly related to the concentration of analyte atoms in the test sample. Argon-based ICP is particularly suitable for exciting a variety of metal atoms and thus facilitates simultaneous multielement capability (Figure 1). By means of an appropriate suite of elemental standards, the instrument can be calibrated. By employing the linear calibration functions obtained for each analyte, one can measure the concentration of these elements in the sample.[1,2,3]

Environmental applications were the driving force in the development of ICP instrumentation. In 1975, under contract to the USEPA, Winge et al.[4] of Ames laboratory reported on the development of ICP-AES for the simultaneous determination of trace element pollutants in water. The USEPA established its first official ICP-AES method for wastewater in 1982 as Method 200.7.[5]

In the 1980s, the decade of ICP, the USEPA approved ICP-AES for the following programs: National Pollutant Discharge Elimination System (NPDES); Safe Drinking Water Act (SDWA); Contract Laboratory Program (CLP); and Resource Conservation and Recovery Act (RCRA). An overview of the USEPA-approved methods for ICP/AES can be found in the *Code of Federal Regulations* (40 CFR, Parts 136 and 141) and in the *Guide to Environmental Analytical Methods*.[6]

This article expands on the USEPA programs listed above, their effect on the growth of ICP-AES for environmental analysis, and recent ''front-end'' developments of several sample introduction methods for ICP-AES.

2 INDUCTIVELY COUPLED PLASMA DESIGNS

ICP-AES gained a strong foothold in environmental laboratories in the 1980s and 1990s due, in part, to the advantages over its predecessor flame atomic absorption spectroscopy listed here:

- multielement analysis capability
- large dynamic linear range
- reduction of matrix interferences
- good long-term stability: <1% (relative standard deviation) RSD with good instruments[2]
- improved detection limits for refractory elements and
- enhancement of productivity.

The early ICP-AES designs of the 1980s that were approved for environmental analysis were of two types: simultaneous and sequential spectrometers with radial viewed torches.[7] The use of the radial viewed plasma results in a shortened path length, which puts the detection limit above the detection limits required by USEPA for elements such as arsenic, lead, selenium, and thallium. For these elements, the USEPA usually required the use of a heated graphite atomizer (HGA).[8]

Later, ICP-AES designs of the 1990s approved for environmental analyses were axial viewed simultaneous and sequential spectrometers.[9] The use of the axial view of the plasma results in a longer path length that greatly improved detection limits and nearly eliminated the need for the use of the HGA to meet the USEPA-detection requirements.[10] With the advent of inductively coupled plasma mass spectrometry (ICP-MS) and by taking the benefit of its high sensitivity and low elemental detection limits, Method 200.8 was first introduced by USEPA in 1990 for the analysis of water.[11]

Recent commercial ICP-AES instruments are not bulky and do not require expensive laboratory space to house them; and they are often bench top versions. In addition, the hardware is more robust, the instrument operational software is user friendly, and the unit price of decent ICP-AES instruments are now more affordable for commercial and research laboratories. During the past 10 years, the major analytical advances in ICP-AES analytical technology have been somewhat slow except for the introduction of solid-state charge transfer detectors and the use of microsample introduction systems including micronebulizer. Solid-state charge transfer detectors (CTD) such as charged-coupled devices (CCDs) and charged-injection devices (CIDs) are common nowadays in commercial instruments. These detectors offer simultaneous multielement capability and have lowered the detection limits obtained by ICP-AES, but further work should be done to minimize the analytical limits imposed by the analytical response at the UV range and issues related to the dynamic range and limited pixilation.[12] These solid-state charge transfer

detectors (CTD) were developed in parallel with the recent development in ICP-mass spectrometry (MS)[2,13] and reviewed by Mermet.[13] Plasma robustness can be evaluated by measuring the signal intensity of Mg(I) (at 285.213 nm) and Mg(II) (at 280.270 nm).[14] Finally, ICP-AES spectrometers that could be programmed for both radial and axial view became the state of the art where the less sensitive radial view was preferred for the higher concentration elements such as aluminum, calcium, iron, magnesium, potassium, and sodium in environmental samples, while the more sensitive axial view was preferred for the lower concentration elements such as the transition series.[15]

3 FRONT-END IMPROVEMENTS IN ICP-AES

The efficient introduction of liquids that offer maximum analytical information is always a challenge for popular pneumatic nebulizer-based ICP-AES techniques. As a result, a series of so-called front-end improvements have taken place during the past two decades (see Figure 1). Some of these improvements were developed in parallel with similar developments in ICP-MS, and some were borrowed from well-established atomic absorption spectrophotometry (AAS). These alternatives include the improvement of nebulizers that can deliver liquids efficiently, introduction of analytes as a gas-phase (i.e. hydride generation (HG) and electrothermal vapor introduction) that will eliminate the introduction of difficult sample matrices, flow injection analysis (FIA) that can introduce small sample volumes that increase the analytical throughput via online analysis, and the separation of elemental species (i.e. As(III) and As(V)) before introduction to the ICP discharge. The former approach has led to the new and exciting field of *chemical speciation* that offered vital analytical information of environmental and clinical interest. For example, As(III) is more toxic than As(V),[16] and the ratio of these species' presence in a given environmental medium is of great importance for an environmental chemist. Resolution of these chemical species requires powerful separation techniques, for example, high performance liquid chromatography (HPLC), gas chromatography (GC), capillary electrophoresis (CE), or size-based separation methods like field-flow fractionation (FFF). These chromatographic or separation methods offer unique chemical and physical separation capabilities before introduction of the separated chemical species to the ICP-based elemental detector. The analytical developments in the chemical speciation area have been noteworthy with ICP-AES, and these advances are extended particularly with ICP-MS. This is partly because the mass spectrometer (MS) is a more sensitive detector than the optical emission detector (OES or aka AES). Some of these so-called front-end improvements are discussed and critiqued at length in the recent literature by Linge,[12] Mermet,[13] Becker,[17] Hansen, and Miró.[18]

3.1 Solution Introduction via Nebulizer

Although the customary method of sample introduction is a pneumatic nebulizer ($\sim$1 mL min^{-1}) that converts the sample liquid into appropriate-sized aerosol droplets that can be introduced into the plasma source for excitation, this approach has been limited by poor sample-/analyte-transport efficiency.[17] The alternative to this technique is to introduce small sample volumes using a microflow nebulizer, and a spray-chamber configuration that provides improved sample transport to the plasma and reduced sample consumption.[2,17,19] A direct-injection, high-efficiency nebulizer, which is widely known as *DIHEN*, can reduce the sample consumption rate down to 30 μL min^{-1}, and it was successfully applied to minimize sample matrix effects in both axially and radially viewed ICP-AES.[20] An attempt has been also made to incorporate a sample introduction system to the ICP excitation source using a microflow nebulizer that is easily snapped to the base of the ICP torch assembly. This torch-integrated sample introduction configuration (*aka* TISIS) has minimized memory effects, and it has been found that matrix effects and nonspectroscopic interferences are minimal.[21] The elemental sensitivity of ICP-AES and MS had enhanced two to five times by the use of ultrasonic nebulizer (USN), in which the sample is nebulized with the aid of a piezoelectric transducer driven by a high frequency generator.[2] Clearly, these advancements are a welcome addition to atomic spectroscopists and can be advantageous in analytical applications where the sample size is limited and improved detection limits are needed. These devices are now available commercially through several manufactures that specialize in front-end ICP spectrometry accessories.

3.2 Hydride Generation (HG)

The premise of the HG method is to produce a gas-phase elemental hydride by a reduction reaction,[22] and to introduce the resulting gaseous hydride (MH_n) directly to the atom excitation/ionization source (i.e. ICP, flame, and furnace). These reducing reactions are rapid, and are usually achieved by the reaction of the sample with an alkaline solution of sodium tetraborate ($NaBH_4$) in an acidic medium (the reducing agent that generates nascent hydrogen). The ensuing hydride ($M^{n+} + (n+2)\,H^+ \rightarrow MH_n + H_2$) formed is flushed with a stream of an inert striping gas like argon. HG reactions

can be achieved on line or by flow-injection modes; therefore, it is convenient for automation. The HG method has been successfully applied for metalloid-based hydrides (AsH_3, SbH_3, and BiH_3) and other elemental hydrides, for example, Ge, Pb, Se, Te, and Sn.[23,24] More recently, the scope of this approach has extended to transition metals (Zn) and noble metals such as Ru and Rh.[25,26] The HG method has enhanced analyte-transport efficiency (from 1 to 100%) and has eliminated most of the matrix-based interferences. As a result, the analytical sensitivity of ICP-AES has improved and lower detection limits have been achieved. Furthermore, the sample is introduced as a gas phase, and the input power to the argon plasma is minimized in contrast with liquid-based sample introduction. Selective reduction and subsequent measurement of inorganic arsenic species (As(III), As(V)), monomethylarsonic acid (MMA), and dimethylarsinic acid (DMA) using continuous HG mode has been demonstrated with ICP-AES.[23,27]

3.3 Chemical Speciation with ICP-AES

Although ICP-AES is not the most sensitive detector for elemental speciation, it has been used effectively in several instances where the sensitivity of ICP-AES is sufficient enough to achieve the detection capability of interested chemical species. The element-based chemical speciation field is dominated by ICP-MS as a sensitive detector for many speciation applications. To accomplish chemical speciation, often chromatography-based separation techniques such as HPLC or GC are required. Once separated, the ions (e.g. different oxidation states of Sb(III) and Sb(V)) or metal-bearing chemical species MMA or diethyl mercury – $(C_2H_5)_2Hg$) can be directly transported into the ICP-AES nebulizer as a sample. The resulting chromatogram (i.e. emission intensity at a selected wavelength vs time) indicates the retention time of the chemical species–associated metals as a peak. The peak area or height can provide quantitative information about these species if an appropriate calibration is made prior to sample analysis. The mobile phase flow rates of HPLC-based separations ($1\,mL\,min^{-1}$) are suitable for interfacing the chromatograph eluent with the ICP-AES detector, thus providing the capability of automation of metal speciation. HPLC-ICP-AES techniques have been successfully applied for selenoamino acids speciation[28] and the study of cobalt–cysteine interactions,[29] while GC-MS-ICP-AES is reported by Kato et al., (1992) using an axial view of ICP-AES.[30] Size-based separation of metals associated with air particulates in PM_{10} fractions were determined by flow field-flow fractionation (flow-FFF) coupled with ICP-AES.[31] The authors used sedimentation (Sd) FFF-ICP-AES and applied USN to overcome the poor sensitivity of ICP-AES and small sample mass and dilutions resulting from the Sd-FFF separation process. Later, Saeseaw et al. used FFF-ICP-AES to distinguish Ca^{2+}- and Zn^{2+}-induced aggregation of β-lactoglobulin aggregates.[32] Application of hyphenated ion chromatography (IC),[33] GC,[34] and CE separation methods to ICP-AES and MS detectors are discussed in the literature.[33,12]

3.4 Flow Injection Analysis (FIA) in ICP-AES

A small, discrete sample is injected to the flowing carrier solution where the dispersion of the sample into the carrier is controlled by the convection current owing to the carrier stream flow and diffusion owing to the concentration difference between the sample and the carrier stream. The introduced sample can be subjected to on-line reagents to carry out predetermined chemistries, or separation or preconcentration of analytes, to prepare for subsequent detection analytes of interest downstream. In this particular case, the detector is a sensitive multielement detector like ICP-AES or ICP-MS. The resulting FIA curve (or ''fiagram'') is a profile of the intensity signal against time. The width of this profile is influenced by dispersion of sample resulting from convection and diffusion forces between the sample and carrier liquids. The recent advancements in FIA analysis are reviewed by Hansen and Miro.[18] FIA has been used effectively to incorporate analysis of hydride-forming elements such as As, Sb, Bi, Se, Te, and Ge,[18] for isolation and preconcentration of aluminum species,[35] for on-line standard addition and dilution of trace metals in plant materials,[36] for speciation of Cr(III) and Cr(VI) species,[37] and for on-line multielement analyses of alkaline salts by ICP-AES.[38] The FIA method facilitates rapid throughput of samples and requires a small sample size, therefore it is an attractive method in terms of time and cost of analysis. FIA may suffer from degraded sensitivity. Nevertheless, FIA methods are as good as most traditional analytical methods as far as accuracy and precision are concerned and the selectivity is often better.[2]

4 ENVIRONMENTAL SAMPLE PREPARATION FOR INDUCTIVELY COUPLED PLASMA/ATOMIC EMISSION SPECTROSCOPY ANALYSIS

4.1 Sources of Information

Sample preparation methods for ICP analysis of trace metals can be found in the following sources:

- The USEPA's Office of Solid Waste prepares and publishes the SW-846 manuals for the analysis of

groundwater, extracts, industrial wastes, soils, sludges, sediments, and solid wastes as dictated by the RCRA.[39]

- The American Public Health Association, the American Water Works Association, and the Water Environment Federation jointly prepare and publish the *Standard Methods* manual for the analysis of drinking water and wastewater.[40]
- The USEPA's Office of Research and Development prepares and publishes its *Methods for the Determination of Metals in Environmental Samples* for the analysis of drinking water, surface water, saline, and industrial and domestic wastes.[41]
- The USEPA published its *Methods for the Determination of Metals in Environmental Samples* Supplement I that updates sample preparation methods.[42]
- The USEPA's Superfund program prepares and publishes its *CLP* manual for the analysis of wastewater and solid waste.[43]

The following method requirements are taken from the SW-846 manuals to provide the reader with an example of what sample preparation for ICP analysis entails. A compilation of approved methods of ICP sample preparation is presented in Table 1.

The sample introduction for ICP environmental applications requires the samples to be in a liquid form so that they can be aspirated through a nebulizer and that suspended solids be removed to prevent clogging of the nebulizer. Therefore, solid samples such as soils and sludges must first be acid digested to extract the metals of interest from the solids, and the resulting digestate must be filtered, centrifuged, or allowed to sit to remove the suspended solids prior to analysis. Drinking water with turbidity greater than 1 (nephelometric turbidity unit) NTU must also be acid digested followed by the removal of suspended solids prior to analysis.

4.2 Hot Plate Digestions

The acid digestion of waters and solids, employing nitric and hydrochloric acids, can be effected by either hot plate (or hot block) methods or microwave methods. The hot plate methods for the preparation of waters can be quite confusing as they are subcategorized as being either ''total'' or ''total recoverable'' – or referred to by some as ''hard'' and ''soft'' respectively – where the ''total'' digestion is more rigorous than the ''total recoverable'' method. An example of a hot plate ''total'' digestion

Table 1 Digestion methods for environmental ICP/AES analysis

Method	Matrix	Reagents	Digestion type	References
3005A	Ground water/surface water	HNO_3/HCl	Total recoverable	16
3010A	Waste water (also applicable to extraction procedure (EP) and mobility-procedure extract)	HNO_3/HCl	Total	16
3015A	Water, mobility-procedure extracts, and wastes that contain suspended solids	HNO_3	Microwave assisted in Teflon vessels	39
3031	Oils and petroleum sludges	Various (HNO_3), H_2SO_4, HCl, $KMnO_4$	Total	39
3040A	Oils	Dissolved and diluted in organic solvent	Dissolution	39
3050B	Soil	HNO_3/H_2O_2/HCl	Total recoverable	39
3050B	Soil	HNO_3/H_2O_2/HCl	Microwave-assisted	39
3051A	Soil, sludges, sediments	HNO_3/HCl	Microwave-assisted	39
3052	Silicates, oil contaminated soils, organic ash, biological tissue	HNO_3/H_2O_2/HCl/HF	Microwave-assisted Total (use fluoro carbon digestion vessel)	39
3030E	Water	HNO_3	Total	40
3030F[a]	Water	HNO_3/HCl	Total	40
3030F[b]	Water	HNO_3/HCl	Total recoverable	40
4.1.3	Water	HNO_3/HCl	Total	41
4.1.4	Water	HNO_3/HCl	Total recoverable	41
200.2	Water/soil	HNO_3/HCl	Total recoverable	42
ILMO4.0	Water	HNO_3/HCl	Total recoverable	43
ILMO4.0	Soil	HNO_3/H_2O_2/HCl	Total recoverable	43
200.7	Water/solids, and bio solids	HNO_3/HCl	Total recoverable	44
200.15	Water	HNO_3/HCl	Total recoverable	45

[a] Total HNO_3/HCl procedure.
[b] Recoverable HNO_3/HCl procedure.

for wastewater is the SW-846 method 3010A and an example of a hot plate ''total recoverable'' method for ground water, surface water, and wastewater is the SW-846 method 3005A. An example of a hot plate digestion for solids, including sludge and soils, is SW-846 3050B.

4.3 Microwave Digestions

Microwave digestion methods using either closed-vessel or open-vessel microwave digestion systems are approved by the USEPA. Examples of closed-vessel microwave methods for wastewaters and solids are the SW-846 methods 3015A and 3051A respectively. An example of an open-vessel microwave method is the SW-846 method 3050B. Finally, the SW-846 method 3052, a closed-vessel microwave method, which employs hydrofluoric acid for the preparation of siliceous and organic-based matrices as well as biological tissue, oils, sediment, soil, and sludges, is the only truly ''total'' digestion approved by the USEPA in which all suspended solids are solubilized.

5 ENVIRONMENTAL INDUCTIVELY COUPLED PLASMA/ATOMIC EMISSION SPECTROSCOPY METHODS OF ANALYSIS

5.1 Sources of Methods

The most used ICP methods of environmental compliant analysis are the USEPA's Office of Research and Development method 200.7 revision 4.4[44] and the USEPA's Office of Solid Waste SW-846 method 6010B.[16] Other environmental ICP methods of analysis that are similar to method 6010B include the standard method 3120B,[40] the CLP,[43] and the air force center for engineering and the environment (AFCEE) at http://www.afcee.af.mil/.

The USEPA also approves the use of its method 200.15 for drinking water analysis.[45] This method employs an USN on the front end of an ICP-AES system to provide better detection limits required for drinking water analysis. It is important to note that the USEPA has not yet approved ICP-AES, with or without ultrasonic nebulization, for the analysis of Pb, Sb, Se, and Tl in drinking water. Effective from January 2006, drinking water supply operators have to comply with the new public health goal (PHG) for arsenic in drinking water promulgated by USEPA in 2002. The new maximum contaminant level (MCL) for As in drinking water is 10 $\mu g\ L^{-1}$.[46] This MCL is routinely difficult to achieve by ICP-AES and consequently the EPA has withdrawn the ICP-AES methods 200.7 and the standard method 3120B for the determination of arsenic in drinking water. Now, one has to use either method 200.9 graphite furnaces (GF)-AAS or method 200.8, which is based on ICP-MS.[46]

The SW-846 method 6010B is used here to provide an example of a typical environmental ICP method. For a comparison of various environmental ICP methods, see Wagner.[6]

5.2 Recommended Inductively Coupled Plasma-atomic Emission Spectroscopy Emission Lines

Table 2, taken from method 6010B, documents the suggested ICP emission line of choice and the estimated instrument detection limit (IDL) for radial viewed plasma. Some programs such as the CLP publish contract-required detection limits (CRDLs) that must be met by the instrument of choice (see Table 3). The CRDLs for Pb, Se, and Tl required by the CLP's Statement of Work (SOW) Inorganic Laboratory Manual Operations (ILMO) 4.0 are 3, 5, and 10 respectively. A radial viewed ICP does not meet these required detection limits. However, an axial viewed ICP meets these

Table 2 Recommended wavelengths and estimated instrumental detection limits (IDLs) for radial view ICP-AES[43]

Element	Wavelength (nm)	Estimated IDL ($\mu g\ L^{-1}$)
Aluminum	308.215	30
Antimony	206.833	21
Arsenic	193.696	35
Barium	455.403	0.87
Beryllium	313.042	0.18
Boron	249.678 × 2	3.8
Cadmium	226.502	2.3
Calcium	317.933	6.7
Chromium	267.716	4.7
Cobalt	228.616	4.7
Copper	324.754	3.6

Reproduced from Ref. 20.

required detection limits and, therefore, has become the instrument of choice for environmental analysis.

5.3 Compensating for Interferences

ICP emission suffers from spectral interferences, and the analyst must document that these interferences have been eliminated. The two most common interferences experienced in environmental ICP analysis are (i) the baseline shift caused mainly by high concentrations of Ca and Mg in samples and due to stray light and (ii) direct spectral overlap due to an emission line from an element in the sample that falls at or near the analyte wavelength and causes a false analyte concentration. Figure 2 shows the effect of both types of interference on the Sb 206.833-nm emission line for an axial view ICP. The calibration standard of 1000-ppb Sb (——) and the calibration blank (- - - -) are superimposed on the graphic that also displays the emission signal for an interference check standard (ICS[A]) with major elements only (-·-·-·-·), which contains 500-ppm Al, Ca, and Mg, and 200-ppm Fe as well as the emission signal for a standard that contains 10-ppm Cr, Mn, and V (· · ·).

If left unchecked, the ICS [A] would give a false positive reading of approximately 800-ppb Sb. To prevent this, a background-correction point is programmed slightly to the left of the Sb calibration standard peak (L). During analysis, the emission at the background-correction point wavelength is subtracted from the emission at the 206.833-nm peak wavelength, which effectively reduces the reading of the ICS[A] to less than detectable.

Referring again to Figure 2, the background-correction point does not reduce the reading from the 10-ppm Cr, Mn, V standard since there is a false peak for Sb arising from one of the three elements in this standard (in this case, the interference is due to Cr). To correct for this direct spectral overlap, an inter element correction (IEC) is required and must be documented.

Figure 2 ICP/AES spectral overlays of the antimony 206.833-nm emission line (——) and a blank (- - - -) in the presence of an ICS[A] (-·-·-·-·) and a mixed standard of chromium, manganese, and vanadium (· · · ·). The overlays are used to set the background-correction position and to verify if inter element correction factors (IECs) are required.

Other interferences normally encountered in environmental ICP analysis are physical or matrix interferences caused by differences in viscosity or the amount of dissolved solids in samples compared to standards. To reduce matrix interferences, analysts are required to prepare all standards and QC samples in the same acid matrix that exists for the digested samples. As a further control, analysts should use an internal standard such as Sc or Y to compensate for physical interferences.

5.4 Quality Control Protocols

After optimizing the instrument according to the manufacturer's specifications, the analyst is required to analyze a number of QC samples throughout the run where there are decisions to be made on the basis of a window of acceptance for each QC sample analyzed.

The concept of the sample batch is used to describe the number of samples (typically a maximum of 20 samples) that are digested prior to ICP analysis and that are accompanied by QC samples that are also digested. The failure of the digested QC samples (see below) to meet acceptance criteria requires that the samples be redigested.

The complete list of the QC samples as per SW-846 method 6010B is given in the following sections.

5.4.1 Initial Calibration

For SW-846 method 6010B, calibration of the ICP-AES requires one calibration standard within the linear range and one calibration blank. The correlation coefficient of linear calibration curve should be at least 0.995 or better.

5.4.2 Initial Calibration Verification Standard

This standard is prepared from a source different from the source used for the calibration of the ICP. The concentrations of the elements should be at a level that is 50% of the concentrations in the calibration standard. The initial calibration verification (ICV) standard is analyzed after initial calibration of the ICP to verify the calibration curve and must fall within an error of ±10% of the true value. The same analytical wavelength used for calibration of the instrument must be used for sample analyses. Any analyte(s) that fails must be reanalyzed.

5.4.3 Continuing Calibration Verification Standard

This is the same as the ICV but the analysis is after every 10 samples and at the end of the run to monitor the drift. If the continuing calibration verification (CCV) standard falls outside the error window of ±10%, then the 10 samples preceding the failed CCV must be reanalyzed for the failed analyte(s). The concentration of this standard should be closer to the midrange of the calibration curve.

5.4.4 Initial Calibration Blank

This contains the matrix acids and is analyzed after the ICV to monitor contamination and memory effects. If the (initial calibration blank) ICB is greater than three times the IDL, the instrument must be recalibrated for the failed analyte(s).

5.4.5 Continuing Calibration Blank

This is the same as the ICB but the analysis is after each CCV. If the continuing calibration blank (CCB) is greater than three times the IDL, then the 10 previous samples must be reanalyzed for the failed analyte(s). However, if any of the 10 previous samples are greater than 10 times the failed CCB, then these sample(s) do not have to be reanalyzed.

5.4.6 Method Blank

This blank is carried through the entire sample preparation process. Although method 6010B does not provide a definitive QC window, laboratories usually assign the same criteria for the method blank (MB) as for the CCB. In other words, if the MB is greater than three times the IDL, then the samples must be redigested for the failed analyte(s) except for those samples that are more than 10 times the failed MB.

5.4.7 Check Standard

A known standard solution is prepared by an external laboratory.

5.4.8 Interference Check Standard

This standard contains 500-ppm Al, Ca, Mg, 200-ppm Fe, and either 500 or 1000 ppb of all the analytes. The normal nomenclature used for this standard refers to the solution containing the major elements only (Al, Ca, Fe, and Mg) as ICS[A]; the solution containing the 500 or 1000-ppb analytes only as ICS[B]; and the combination of the two solutions as ICS[AB]. The ICS[AB] is used to verify that the background-correction points and the IEC values are programmed correctly. Any analyte(s) that falls outside the error window of ±20% must be reanalyzed.

5.4.9 Matrix Spike/Matrix Spike Duplicate

One duplicate sample is spiked with a known concentration of analytes and is carried through the entire sample preparation process. A separate MS/MSD (matrix spike/matrix spike duplicate) must be prepared for waters, soils, and extracts. The relative percent difference (RPD) of the matrix spike duplicate (MSD) must fall within ±20% error and the spike recovery must be within ±25% error.

5.4.10 Additional Quality Control

In the event that the matrix spike fails to fall within the allowed 75–125% recovery limits, the analyst must perform (i) a dilution test and (ii) a postdigestion spike addition.

1. Dilution test – a 1:5 dilution of the sample is prepared only if the analyte concentration is greater than 10 times the IDL after dilution. The diluted concentration must agree with the undiluted concentration within ±10%.
2. Postdigestion spike addition – a spike containing the analytes at concentration between 10 and 100 times the IDL is added to the digested sample. The spike recovery must be within 75 – 125%.

5.4.10 Preanalysis Quality Control

Prior to any analysis, the following data must be gathered for each ICP-AES emission line:

Table 4 SW-846 method 6010B ICP/AES run log

Sample	QC error limits
Calibration blank	
Calibration standard	
ICV standard	±10%
ICV blank	<3 × IDL
ICS[A]	±20%
MB	<3 × IDL
Sample 1	
Sample 1 + MS	±25%
Sample 1 + MSD	±20% RPD
Sample 2	
Sample 3	
Sample 4	
Sample 5	
Sample 6	
CCV standard	±10%
CCV blank	<3 × IDL
Sample 7	
Sample 8	
Sample 9	
Sample 10	
CCV standard	±10%
CCV blank	<3 × IDL

- linear dynamic range;
- method detection limits;
- IDLs (instrument detection limits, the concentration equal to an analytical signal resulting from three times the blank signal = $3^{*}\sigma_{b}$, measure 7 [n] replicates);
- IEC factor determined by aspirating a solution with major concomitant ions such as Ca, Mg, Al, and Fe; and
- background-correction points.

A typical run log for ICP-AES analysis that follows the SW-846 method 6010B is shown in Table 4.

ACKNOWLEDGMENTS

The author would like to thank Oliver Fordham, Jr. of the USEPA Office of Solid Waste and Emergency Response for his input on the historical aspects of the USEPA methods of ICP-AES analysis, and Kathy Zinn of Progress Environmental Laboratory and Dr. Ramon Barnes of University Research Institute for Analytical Chemistry, Amherst, MA for their review and critique of the various parts of this manuscript.

The analysis of environmental samples typically focuses on aliphatic short-chain organic acids. The origin of these organic acids and the motivation for their analyses are unique for each type of matrix. Environmental sample matrices are very diverse and can range from air and atmospheric precipitation such as fog, rain or snow to wastewater, drinking water or landfill leachates and soil pore water. This diversity in matrix leads to substantial differences in organic acid concentrations and different organic acid distributions in the various types of environmental samples. Hence, the analytical techniques employed have to be adapted to the particular matrix under investigation.

*Ion chromatography is one of the most commonly used techniques for organic acid analysis. Competing ion chromatographic methodologies are anion (ion)-exchange chromatography (IC) and ion exclusion chromatography (ICE). The separation principles underlying each of these techniques are very different and may be used to their advantage. In IC, anions are separated by anion exchange processes between the cationic exchange groups on the resin and the eluent. Hence, inorganic anions and carboxylate anions may be analyzed at the same time (e.g. rain). Limitations of this technique set in when the inorganic anion concentration is much larger than the carboxylate concentration. As a consequence, inorganic anion peaks may mask or co-elute with the analyte of interest. However, techniques have been developed to handle this problem, for example in drinking-water analysis. The separation mechanism in ICE is much more complex than in IC involving Donnan exclusion, adsorption and steric exclusion. ICE is generally used for the separation of weak organic acids since strong organic acids elute in the system peak in the front of the chromatogram. Hence, large concentrations of strong inorganic anions, for example sulfate or chloride, will not interfere with the analysis of weak organic acids. However, organic acids with relatively low p*Ka values may be difficult to separate from the system peak. In addition, weak inorganic acids such as carbonate have the potential to interfere with the analysis of certain organic acids if present in large enough concentrations.*

Other techniques than ion chromatography have been used for organic acid analysis. Direct injections of samples into a gas chromatograph are very common for measuring volatile fatty acids (VFAs) in wastewater. More complex gas chromatography (GC) methods, which include concentration and derivatization steps, have been employed to analyze for specific types of organic acids such as dicarboxylic acids in rain. Capillary electrophoresis (CE) is a newer technique, which has not been used widely in routine analysis. However, speciality applications such as the determination of organic acids in a single raindrop show the potential of this type of methodology.

1 INTRODUCTION

Organic acids are hydrocarbons, which are characterized by their carboxylate function. Their hydrocarbon structure can vary considerably resulting in a wide range of organic acids with different physical and to a certain

extent chemical properties. The analysis of environmental samples typically focuses on aliphatic short-chain organic acids. The most common ones are listed together with their structure and p*K*a values in Table 1. The origin of these organic acids in environmental samples and the motivation for their analyses varies from matrix to matrix as outlined in the background section. Table 2 gives an overview of the different types of environmental sample. A brief general discussion of the ion chromatographic techniques commonly utilized and their advantages and disadvantages with respect to the organic acid analysis follows.

2 BACKGROUND

2.1 Air and Atmospheric Precipitation

Organic acids in rain were first detected in the 1970s.[4] They also have been found to be present in air and all other forms of wet atmospheric precipitation such as fog, snow and ice. Possible sources of emission are reported to be of anthropogenic as well as biogenic origin. However, little information is available about biogenic sources.[5] Direct sources of anthropogenic emission include vehicle exhaust fumes[6,7] and combustion of coal or wood.[8–10] Directly emitted hydrocarbons can be viewed as indirect anthropogenic sources of organic acids in the atmosphere. These hydrocarbons presumably act as organic precursors, which are oxidized through complex photochemical reactions into organic acids. The ongoing discussion in the literature indicates that it is difficult to elucidate the interactions and the detailed reaction mechanisms of the radicals involved, especially when taking into account the role of the gaseous phase, the water phase and adsorption processes onto particles.[10–12]

Formic and acetic acid are usually present in much higher concentrations in all of these matrices than any of the other organic acids detected, including dicarboxylic and ketoacids. The total amount of organic acids can be quite significant. It is reported that in North American rain up to one-third of the total free acidity is caused by organic acids.[13,14] However, it is postulated that organic acids do not contribute significantly to the long-term acidification of the environment since they are easily biodegradable.[13] Research is focusing on gaining more insight into reaction mechanisms as well as cataloging possible emission sources of organic acids.

Table 2 Types of environmental sample

Matrix	Type of organic acid	Expected organic acid concentration	Other matrix characteristics
Air	Mainly formic and acetic acid	Very low ppbv = low $\mu g\,L^{-1}$ volume	SO_2, NO_x, CO, O_3 at low to medium ppbv Particles present too
Rain, snow	Formic and acetic acid predominate Other mono- and dicarboxylic acids, keto- and hydroxy acids	Low to high $\mu g\,L^{-1}$ depending on organic acid species and location	Inorganic cations and anions at $\mu g\,L^{-1}$ especially SO_4^{2-}, Cl^- and NO_3^- Other organic compounds such as hydrocarbons from fuel emissions or terpenes from natural biogenic sources
Ice	Acetic and formic acid most abundant, some glycolic and oxalic acid	Low $ng\,g^{-1}$	Inorganic anions at low $ng\,g^{-1}$
Groundwater, soil pore water	Monocarboxylic acids especially acetic acid	Low to high $\mu g\,L^{-1}$ depending on location and other factors	Vary depending on geology, contamination, location etc.
Drinking water (incl. raw and treated water)	Ozonation by-products: Predominantly acetic, formic and oxalic acid Other mono- and dicarboxylic acids, hydroxy and ketoacids	Low to medium $\mu g\,L^{-1}$	Inorganic anions and cations at low to medium $mg\,L^{-1}$ Other organic compounds: typical TOC 2–7 $mg\,C\,L^{-1}$
Wastewater	Predominantly aliphatic, monocarboxylic acids (C_1–C_7 = VFA) especially in anaerobic digesters	High $mg\,L^{-1}$	Medium to high $mg\,L^{-1}$ of inorganic cations and anions High concentrations of organic compounds
Landfill leachates	Monocarboxylic acids, keto- and hydroxyacids	Low to medium $mg\,L^{-1}$ depending on type of acid and age of landfill	Medium to high $mg\,L^{-1}$ of inorganic cations and anions High concentrations of organic compounds

TOC, total organic carbon.

2.2 Groundwater

Organic acids can be found close to seeps of naturally occurring hydrocarbons into groundwater, or in the proximity of groundwater sites contaminated with petroleum hydrocarbons. Biodegradation of these hydrocarbons under the anaerobic conditions of the groundwater aquifer leads to a variety of metabolic intermediates, especially organic acids.[15,16] Although it is expected that the organic acid intermediates are structurally related to the original hydrocarbons, high concentrations of short-chain aliphatic organic acids are most commonly observed, even when aromatic hydrocarbons are the original source. The localized concentration of formate, acetate and isobutyrate combined may be as high as $9000\,\mu mol\,L^{-1}$,[17] but varies considerably depending on the rate of organic acid production and consumption. Hence, factors such as the proximity to the hydrocarbon source, hydrocarbon loading, presence of microbial inhibitors, availability of nutrients and availability of electron acceptors affect the organic acid concentration in groundwater.

The main effects of high organic acid concentrations in groundwater are mineral dissolution, which leads to changes in soil structure, and complexation of metals such as Fe or Al, which may subsequently be mobilized into the aquifer.[17] Hence, it is important to take the organic acid production and its consequences into account when observing and projecting the transport of hydrocarbon contamination in groundwater[17] and when estimating changes in the porosity of oil reservoirs due to organic acid formation in oilfield water.[18,19]

2.3 Drinking Water

Ozone is frequently applied during drinking-water treatment, mainly for disinfection purposes but also to break down taste and odor compounds. Other reasons for its utilization include color removal and pretreatment.[20] In Europe, ozone has been established in many drinking-water treatment plants for quite some time, whereas in North America, it has only gained interest since the late 1980s. In North America, ozone is often applied with the intention of reducing chlorinated disinfection by-products further by partially substituting chlorine with ozone as the disinfectant.

However, organic compounds which are present naturally, especially in surface water, are oxidized during ozonation, and organic acids and aldehydes are formed as well as a range of other products. Various short-chain aliphatic organic acids (for example formate, acetate and oxalate) have been identified and quantified in partially treated water as a result of the utilization of ozone during drinking-water treatment.[21–26]

Concentrations of aliphatic organic acids are highest in the effluent of ozone contactors, where they may reach concentrations of $250\,\mu g\,L^{-1}$ for formate or $195\,\mu g\,L^{-1}$ for acetate.[25] Subsequent steps in the drinking-water treatment process reduce these concentrations to low microgram per liter levels or remove them completely.[25] The finished drinking-water is then transported to the customer through a drinking-water distribution system, where any remaining organic acids may contribute to bacterial regrowth, since they are a good nutrient source for microorganisms. Current research conducted in cooperation with the drinking-water industry continues to assess the formation, the removal and the impact of ozonation by-products such as organic acids.

2.4 Wastewater

Organic acids are produced in high milligram per liter concentrations during wastewater treatment in anaerobic digesters. These acids are called VFAs and are defined as ''water soluble fatty acids which can be distilled at atmospheric pressure''.[27] VFAs comprise monocarboxylic aliphatic organic acids with chain lengths of up to seven C-atoms.

Wastewater usually has a high organic carbon (OC) content, which needs to be reduced before the water is discharged into the receiving water body. This is often accomplished by a two-step biological degradation in anaerobic digesters.[28,29] First, acidogenic bacteria convert the OC into VFAs with acetate being the major product, followed by metabolization of these VFAs by methanogenic bacteria into methane. These two processes have to be in balance to ensure successful treatment. The difficulty lies in the fact that methanogenic bacteria metabolize at a slower rate than the acidogenic bacteria. In addition, methanogenic bacteria are usually more susceptible to sudden changes in their environment than the acidogenic bacteria.[28–30] Hence, it is possible that VFAs may not be consumed at the same rate as they are produced, with the consequence that VFA concentrations increase. This in itself may disturb the balance between these processes even further.

Daily monitoring of VFAs is utilized as a sensitive measure of the status of the OC biodegradation. Changes in VFA concentrations indicate disturbances of the biodegradation at an early stage, therefore, making VFA measurement a valuable operational tool in wastewater treatment.[28,29]

2.5 Landfill Leachates

The anaerobic degradation of organic waste in landfills passes through several stages.[31] During the acidogenic phase organic acids, mainly VFAs, are formed in high concentrations and consequently contribute significantly to the OC concentration in landfill leachates. One problem associated with VFA production is the possible mobilization of heavy metals out of the landfill. This is especially of concern when older landfill sites are involved. Older landfill sites often have no liner or only incomplete seals towards the groundwater aquifer and heavy metals may actually be transported into the groundwater.

By monitoring VFA concentrations in landfill leachates, the degradation stage of the landfill itself can be determined. Once VFA concentrations are rising, precautions can be taken to prevent leaking of mobilized heavy metals into the groundwater.

3 ION CHROMATOGRAPHY

3.1 Ion Exchange Chromatography Versus Ion Exclusion Chromatography

Ion chromatographic techniques commonly used for the determination of organic acids are IC and ICE which differ significantly in their separation mechanisms.

In IC, separation is primarily accomplished through partitioning of the analyte ions between the mobile phase and the ion-exchange groups bound to the surface of the column resin. Secondary mechanisms may involve adsorption processes. IC columns for the separation of anions are comprised of a copolymer core, usually divinylbenzene crosslinked with polystyrene, to which modified quaternary ammonium groups are bound on the surface. With the development of membrane suppressors, conductivity detectors have found widespread use in IC. They allow for very sensitive detection of ions by suppressing the background conductivity of the mobile phase, which usually consists of hydroxide, borate, bicarbonate or carbonate. Other detectors utilized in IC include amperometric and UV (ultraviolet)-detectors. IC is normally applied to the analysis of strong inorganic ions. However, compounds such as organic acids, which dissociate at the high pH of the mobile phase into ions, may also be analyzed by IC. Depending on the matrix, inorganic anions and carboxylate anions may be determined at the same time, although separation becomes difficult when the concentration of inorganic anions is much higher than

the concentration of organic acids. This may even result in co-elution and hence masking of organic acid peaks, rendering the particular method unsuitable for organic acid analysis.

Separation in ICE is a much more complex process than in IC and involves Donnan exclusion, adsorption and steric exclusion. ICE columns have high capacities and are usually composed of totally sulfonated divinylbenzene/polystyrene copolymers, which carry strong cation exchange groups. Traditionally UV detection predominates, although conductivity detection is becoming more common. Eluents applied in ICE are aqueous solutions of acids. Dilute mineral acids are mainly in use as eluents in combination with UV detection, whereas strong organic acids such as methanesulfonic or octanesulfonic acid are in use in combination with suppressed conductivity detection. Owing to its specific separation mechanism, ICE is mainly applied to the analysis of weak organic acids in complex matrices. Anions of strong acids, for example sulfate or chloride, elute with the system peak at the front of the chromatogram, thus making this technique suitable for the determination of weak organic acids in samples with high concentrations of strong inorganic anions. Nevertheless, weak inorganic acids, for example carbonate, elute between the organic acids and may, if present in sufficiently high concentrations, interfere with the analysis of the organic acids. In addition, organic acids with relatively low p*K*a values may be difficult to analyze with ICE, since they elute early, close to the system peak.

More detailed descriptions of theoretical background, instrumentation and applications in IC and ICE can be found in books by Weiss[32] and by Haddad and Jackson.[33]

4 SAMPLING AND PRESERVATION

Sampling itself is an important part of the overall analytical process. The ideal sampling technique is adapted to the matrix being sampled, prevents contamination and results in an unaltered sample which reflects the average content of the analyte at the time when the sample was taken. To fulfill these criteria different procedures are applied for different types of matrices. A summary of different sampling techniques is given in Table 3.

When dealing with very low concentrations of organic acids, contamination with the almost ubiquitously present organic acids has to be avoided. It was found that organic acids are present on the human skin and wearing gloves is highly advisable in order to minimize contamination from this source.[53]

4.1 Air

Air samples are usually taken by pumping ambient air for a defined time interval, first, through a Teflon® prefilter to remove particles, and then through a device which retains the organic acids. Devices and processes used for this purpose include filters, scrubbers, denuders, condensation or cryogenic trapping.[34,35,49–51,54] Solutions used in scrubbers may be water or alkaline solutions.[34,35] Filters are also impregnated with alkaline solutions[11,36,51] and denuders are coated with either NaOH or KOH.[37,49] Contamination of these sampling devices with the ubiquitous organic acids is easy. Precautions include thorough cleaning of the sampling devices accompanied by regular measurements of blanks. Another problem is the possible formation of artifacts during long sampling periods in the presence of alkali and/or water which makes

Table 3 Summary of sampling techniques

Matrix	Technique used	Comments	Refs.
Air	(a) Scrubber (b) Denuder: NaOH or KOH coated (c) Filters impregnated with KOH or Na_2CO_3 (d) Cryogenic trapping	• Sampling time varies from 30 min to several hours • DLs depend on sampling time • Contamination of water phase possible • In alkaline solutions formation of acetate from PAN possible	(a) 34, 35 (b) 49, 37 (c) 11, 51, 36 (d) 50, 51
Rain	(a) Setup varies from bottle + funnel to fully automated wet only collection systems (b) Collection of individual raindrops possible	(a) Collection either by rain event or in bulk (b) Analysis only by micro HPLC or CZE	(a) 4–6, 13, 14, 38–46 (b) 47, 52
Ice	Drill cores	Contamination of outer core unavoidable. Remove outer layers prior to melting	48
Groundwater	Well with screen Utilize pump or bailer	Pump until pH and conductivity are stable, then take sample	15, 16
Drinking water	Use sampling ports or bailer	Flush sampling line until stagnant water is removed	–

DL, detection limit; PAN, peroxyacetylnitrate; HPLC, high-performance liquid chromatography; CZE, capillary zone electrophoresis.

it difficult to distinguish between organic acids trapped from the air and those formed while sampling.[34,50]

Recoveries and DLs in particular vary considerably between these different sampling techniques. DLs can be as low as 10 pptv for formic and acetic acid when utilizing the more established scrubber (recoveries 55–98%)[35,50] or the relatively new cryogenic trapping technique (recoveries 100%).[50] When utilizing filters or denuders, DLs are considerably higher (20–450 pptv), though recoveries between 84 and 99% ensure reliable data.[50]

4.2 Rain

Rain collectors, which are typically set up high above ground, for example on rooftops, consist of a collection container and a funnel. Materials utilized are glass, polyethylene, Teflon® and stainless steel. The design of rain collectors varies from a simple setup like a wide neck bottle with a funnel, which is operated manually, to sophisticated automatic wet-only collection systems.[4–6,13,14,38–46] The rain collectors must be scrupulously cleaned before each sampling in order to avoid contamination.

Generally, rain collectors are kept shut until the rain event starts so that dry deposition is excluded from sampling.[38] Rainwater is sampled either by rain event or, less frequently, in bulk. When collecting in bulk, rain collectors are replaced after a defined time period. Although this makes operation relatively easy, samples represent only an average of all of the rain events during the past time interval. When sampling by rain event, collectors are exchanged after a single rain event resulting in an average sample of this specific event.

It is also possible to collect individual raindrops, classify them by size and analyze them for organic acids as well as for inorganic cations and anions.[47,52] This is accomplished with a so-called 'Guttalgor'. Raindrops entering this collection system during a brief opening period freeze immediately when they come into contact with liquid nitrogen and sink to the bottom of the vessel. The frozen raindrops may then be grouped by size by using sieves with different mesh ranging from 0.1–1.0 mm. The analysis of these individual raindrops with their extremely small volume is accomplished by either CE or micro HPLC.[47,52]

4.3 Ice

Ice is sampled by drilling cores. These cores are divided into segments which are then analyzed individually. By relating each segment to its date of origin, information can be gained about the composition of the atmosphere in the past.[10] The organic acid concentration in ice from remote areas is usually quite low and care has to be taken to avoid contamination. It was shown that it is not possible to avoid contaminating the outer parts of ice cores considerably with organic acids and ions during the sampling process. These outer layers have to be removed and only the inner parts of the ice core should be used for analysis.[48] Even extended exposure of the melted ice to the laboratory atmosphere may result in contamination with organic acids.[48]

4.4 Groundwater

Groundwater samples are taken from wells by using either a bailer or a pump. To get a representative sample substantial volumes of groundwater have to be removed until pH and conductivity are stable. Only then should the actual sample be taken.[16] Contamination should be avoided by working with clean equipment and storing samples in clean glass containers.

4.5 Drinking Water

Most drinking-water treatment plants have special sampling ports at the different stages of their treatment process. Before taking samples, the lines leading to these ports need to be flushed thoroughly until the water at the sampling port has the same composition as the water at this particular stage of the treatment process. In plants which do not have these sampling ports, bailers have to be used. During sampling, skin contact should be avoided since organic acids are present in significant concentrations on the human skin.[53] Wearing gloves was found to be an appropriate measure to minimize contamination from this source.

4.6 Preservation

Preservation is closely related to the sampling procedure and the measurement technique applied. Ideally it should ensure stable concentrations of the analytes during sample storage while being compatible with the measurement technique utilized later.

The use of IC or ICE techniques requires the sample to be in a liquid aqueous phase prior to injection. If samples are not already in this form, analytes are transferred into the aqueous phase (for example extraction of filters from air samples with deionized water). Samples are usually stored at 4 °C. However, several authors found this to be insufficient to prevent organic acid losses due to biological degradation.[13,39,53,55] As a consequence, preservatives, usually chloroform or mercuric chloride, are added to aqueous samples. When using IC or ICE for sample analysis, adding a small volume of neat chloroform is the preferred preservation technique, since this does not interfere with the measurement.[13,39,42,53,55] In contrast, when using mercuric chloride as a preservative, the mercury cation has to be removed prior to injection (e.g. by

passing the sample through a cation exchanger) in order to prevent poisoning of the IC or ICE column.[24] Hence, mercuric chloride as a preservative is more prevalent in the context of GC measurements.[15,16,43–46] Another, although less common preservative for environmental samples is benzalkonium chloride, which was recently utilized for stabilizing drinking-water samples.[26]

Freezing samples is another option for sample preservation. Ice cores are usually kept frozen and melted just before their measurement.[10,48] Filters used for sampling air may be stored at $-4\,^{\circ}C$ or $-20\,^{\circ}C$ until they are extracted with deionized water in preparation for their measurement.[11,34,51] Sometimes aqueous sample solutions are also stored at subzero temperatures.[56]

5 SAMPLE PREPARATION AND MEASUREMENT

Sample preparation and measurement are intertwined but differ from matrix to matrix. A summary of methods discussed herein, sorted by matrix can be found in Table 4.

5.1 Air

Concentrations of organic acids in air are quite low (very low parts per billion by volume concentrations). They are significantly lower than concentrations of trace gases such as NO_x or CO. During the sampling procedure and the subsequent sample preparation organic acids are enriched, resulting in aqueous solutions which contain organic acids in low micromol per liter concentrations.

If alkaline filters or denuders are used as the main trapping device, sample preparation consists in extraction with either deionized water or eluent followed by preservation.[34,49] If using a scrubber, condensate process or cryogenic trapping as the main sampling technique,[12,34,50] aqueous solutions are the result and no further sample preparation is required other than immediate preservation. Prefilters, which are used to remove particles prior to air sampling, may be extracted as well. First they are wetted with methanol and then extracted with either deionized water or eluent.[34] The organic acids extracted from these prefilters have been adsorbed onto particles, which were trapped with these prefilters.

All these extracts contain inorganic anions in addition to the organic acids. Fortunately, inorganic anions are present in relatively low concentrations and thus do not interfere with organic acid separation. Organic acid analysis focuses mainly on formate and acetate utilizing both IC and ICE methods, with IC being applied more frequently.[12,34,49–51] Standard columns and conditions are employed as described briefly in Table 4. Additional organic acids such as pyruvate or oxalate may also be analyzed.[12,50,61] If utilizing newer columns, which have been developed for the determination of organic acids, an even wider range of organic acids may be analyzed.[41]

5.2 Rain and Snow

Sample preparation for snow samples consists merely of melting, filtration if necessary and preservation. Organic acid content in rain and melted snow range from low to high micrograms per liter concentrations depending on location, precipitation event and type of acid.[4–6,13,14,39,40,42–47] The more predominant inorganic anions in rain (such as sulfate, sulfite, nitrate and chloride) usually display a somewhat higher concentration.[50] However, in these concentrations they do not cause any major difficulties for the separation of organic acids from inorganic anions. Again, formate and acetate are the major acids of concern and samples may be analyzed by the same standard IC and ICE methods utilized for the analysis of organic acid in air-sample extracts (Table 4). Better yet, some newer IC methods allow for the determination of additional acids such as oxalate as well as for the codetermination of various common inorganic anions (F^-, Cl^-, NO_2^-, NO_3^-, Br^-, SO_3^{2-}, SO_4^{2-} and PO_4^{3-}).[40,41] Hence, these newer IC methods may be preferred over ICE methods, which by nature are only capable of determining weak organic acids.

5.3 Ice

When drilling ice cores it is generally unavoidable to contaminate the outer ice core layers. Hence, these layers have to be removed prior to melting the ice and preserving the resulting solution.[48]

Ice from remote areas usually contains very low concentrations of organic acids and inorganic anions (i.e. low nanograms per gram concentrations). In order to measure these low concentrations organic acids have to be enriched. Utilizing a concentrator column on-line with an analytical column achieves the required low DLs while keeping the sample preparation at a minimum. Concentrator columns suitable for this purpose are small high-capacity anion-exchange columns, which retain the carboxylate anions quantitatively upon loading, if appropriate conditions have been chosen. ICE columns cannot be used as concentrators since water itself acts as an eluent with the consequence that organic acids are not retained quantitatively.

In order to analyze organic acids in ice samples, anion-exchange concentrators have been combined successfully either with an anion-exchange analytical column or with an ICE analytical column.[48,57] Organic acids determined with these setups are either propionate and butyrate, or

Table 4 Method overview organized by matrix

	Type of column[a]	Eluent	Detector[b]	Compounds	DLs	Comments	Refs.
Air							
IC	AG 9, AS 9	$Na_2B_4O_7$ 1 M	Cond. A	Acetic, formic acid	0.1 ppbv[c]	Filters stored at subzero temperatures	51
IC	AS 11	NaOH gradient	Cond.	Acetic, formic, pyruvic, oxalic acid	[c]	Simultaneous detection of inorganic anions possible (Cl^-, NO_2^-, SO_4^{2-}) Sampling with cryogenic trapping	50
IC	AS 4	$NaHCO_3$ 0.4 mM	Cond. A	Formic, acetic, pyruvic acid	0.02–0.1 µM (IC limits)	DLs for 60 min sampling interval: 5–20 pptv Matrix: mist	12

IC	AG 11[d], AG 11, AS 11	NaOH gradient	Cond.	Formic, acetic, glycolic, oxalic acid	20–40 µg L^{-1}; concentr. 0.1–0.5 µg L^{-1}	Sample matrix: Ozonated model water. No testing on "real" drinking water samples described	60
Landfill Leachate							
ICE	(a) Polyspher, OA-HY (Merck) (b) HPICE, AS-6 (Dionex)	(a) H_2SO_4; 5 mM and 50 mM (b) PFBA 0.4 mM and 1.6 mM	(a) UV at 210 nm (b) Cond. D	Formic to *n*-valeric acid, pyruvic, glyoxylic, glycolic, lactic, glyceric, succinic acid	na; analyzed from 50 to 50 000 µM	Sample stored frozen	56

na = not available. MRL, minimum reporting level; PFBA, perfluorobutyric acid; MSE, methanesulfonic acid.

[a] Columns: Columns are manufactured by Dionex if not mentioned otherwise. AG refers to guard columns, AS refers to analytical columns, ATC-1 is the anion trap column used to purify eluents.

[b] Detection: Cond. is the conductivity detection, no further details available, Cond. A is the chemical suppressed conductivity detector using H_2SO_4 as regenerant, Cond. B is the suppressed conductivity detection in auto suppression mode, Cond. C is the suppressed conductivity detection in external water mode, Cond. D is the chemical suppressed conductivity detector using tetrabutylammonium hydroxide as regenerant.

[c] DLs vary with sampling time for air samples.

[d] Used as concentrator column.

glycolate and oxalate, in addition to formate and acetate. The newer method using the IC/IC combination[48] achieves lower DLs than the IC/ICE method. Moreover, the IC/IC method has the added advantage over the IC/ICE method[57] in that inorganic anions (F^-, Cl^-, NO_2^-, NO_3^-, SO_4^{2-}) can be determined within the same chromatogram as the organic acids.

Concentrator column use is limited by the fact that the analytes have to be retained quantitatively. If anions with strong affinities to the anion-exchange concentrator resin such as inorganic anions are present in higher concentrations, carboxylate anions may be forced off the concentrator column during the loading process, thus leading to irreproducible injections and, hence, irreproducible results. However, inorganic anion concentrations in ice samples are usually low enough so that overloading of the concentrator is very unlikely. Nevertheless, the possibility of column overloading should always be taken into consideration when working with concentrators.

5.4 Groundwater and Soil Pore Water

When dealing with samples from contaminated groundwater sites, organic acid content and matrix can vary significantly depending on factors such as type of contamination, proximity to the contamination and geology. Therefore, organic acid content can fluctuate from low to very high microgram per liter concentrations.[15,16] Inorganic anion concentrations as well as type and concentration of contaminants also differ widely from site to site. As a consequence, analytical techniques may have to be adapted to the particular sample matrix.

Another aspect of dealing with contaminated groundwater sites is the possible presence of organic solvents and/or metals in these samples. Columns should be compatible with these specific organic solvents, and metals should be removed from the sample prior to injection by passage through H^+ cartridges in order to prevent column poisoning. Nevertheless, filtration is often the only sample preparation step employed in the IC and ICE methods described below.

An ICE method with standard conditions has been successfully applied to organic acid analysis of samples from a groundwater site, which has been contaminated with petroleum hydrocarbons.[58] Similar ICE methods have been used in the analysis of extracts derived from air samples, and therefore, may also be utilized for groundwater analysis (Table 4). One advantage of ICE methods is the fact that anions derived from strong acids such as mineral acids elute with the system peak at the front of the chromatogram. Hence, inorganic anions such as chloride or sulfate will not interfere with the separation of weak organic acids, even if present in higher concentrations.

Anion-exchange chromatography has been used for organic acid determination in soil pore water[41] and may also be used for organic acid quantification in a contaminated groundwater matrix, although inorganic anions might interfere with the separation of specific organic acids (for example sulfate/oxalate), especially if they are present at much higher concentrations than the organic acids. Similar problems are encountered during drinking-water analysis, which is why strategies applied in drinking-water analysis may also be utilized for groundwater samples containing high inorganic anion concentrations.

5.5 Drinking Water

Organic acids in drinking-water including partially treated water are only present at low microgram per liter concentrations, if at all. The exceptions are effluents from ozone contactors, an accepted drinking-water treatment practice, where organic acid concentrations may reach medium microgram per liter levels.[22,24–26] In contrast to other matrices, concentrations of inorganic anions (Cl^-, SO_4^{2-}, CO_3^{2-} ...) in drinking water are much higher compared to organic acids, ranging from low to medium milligram per liter concentrations.

Although different approaches have been taken, it is surprising that no ICE methods for organic acid analysis in drinking water are reported in the current literature. Problems anticipated when using ICE include interferences from weak inorganic acids such as carbonate and separation problems between the early eluting system peak and organic acids with low p*K*a values such as oxalate or pyruvate.

Anion-exchange chromatography has been used to determine organic acids in drinking water, although very low concentrations of carboxylate anions have to be measured in the presence of large, possibly interfering, inorganic anion concentrations. Slightly different approaches have been taken in the few IC methods dealing with this analytical problem. The focus is usually on formate, acetate and oxalate, although a few other organic acids may be determined as well.

Injection of large sample volumes (for example 760 μL) is one way of ensuring low DLs.[53,55] Owing to the so-called ''relaunch effect''[33] analytes are focused into a relatively small band at the beginning of the column resulting in a chromatogram with narrow peaks, even when injecting larger sample volumes. Subsequent separation is accomplished by a gradient developed specifically for this purpose on a standard anion-exchange column. However, very high concentrations of sulfate can obscure the oxalate peak to the extent that its quantification is impossible. For this type of sample, a two-phase switching technique may be used.[55,59] First, samples

are injected and separated in the manner described previously. At the time window when oxalate is known to elute, the column effluent is redirected onto a concentrator column where the oxalate is trapped. Subsequent reinjection of the concentrator contents onto the same analytical column and application of a different specific gradient makes the quantification of oxalate possible.

In another IC method Hg^{2+} cations, which were initially added to the samples for preservation purposes, have to be removed prior to injection in order to avoid column poisoning.[24] This is accomplished by putting a H^+ cartridge, which is exchanged daily, in line just before the injection valve.[24,26] Separation takes place on a specific organic acid column with subsequent suppressed conductivity detection. Utilization of the H^+ cartridge is also essential for achieving satisfactory chromatograms, since otherwise organic acids eluting before chloride display broad, plateau-type shapes instead of narrow peaks. Although the injection volume is only 50 µL, sufficiently low DLs are achieved.[24,26]

A different approach is to remove chloride and sulfate before IC measurement through pretreatment with barium and silver cartridges.[60] This should be followed by passing the sample through a H^+ cartridge, so that Ag^+ cations, which may have leached into the sample from the previous Ag^+ cartridge, are trapped thus preventing poisoning of the analytical column with Ag^+ cations. A very similar pretreatment procedure is used for low-level bromate analysis in drinking water.[62,63] The treated sample may be injected directly into the ion-exchange chromatograph, where organic acids are separated on a specific organic acid column followed by suppressed conductivity detection. DLs are 20–40 µg L^{-1} for an injection volume of 25 µL.

Using the same approach these limits can be lowered substantially by introducing a concentrator column.[60] The pretreated sample is passed through a strong anion-exchange concentrator column, where the carboxylate anions and other anions are retained. The trapped anions are then eluted from the concentrator onto the separation column in the opposite direction to the loading process. Separation and detection are performed in the same manner as for the direct injection. However, different matrices can contain widely varying concentrations of inorganic anions. Although the majority of the inorganic anions are removed during pretreatment, in the case of very high concentrations this pretreatment may be insufficient. Inorganic anions that remain in the sample may lead to overloading of the concentrator column. Consequently, the less strongly retained carboxylate anions are partially eluted from the concentrator column during sample loading thus leading to irreproducible results. It is therefore important to prevent any breakthrough of the carboxylate anions on the concentrator column when using this method.

5.6 Wastewater

Wastewater, especially from anaerobic digesters, displays a high content (milligrams per liter concentrations) of VFAs, which comprise short-chain aliphatic organic acids. The wastewater matrix is quite complex with very high concentrations of organic material and inorganic compounds.[28,29] Landfill leachates have a very similar composition and may therefore be analyzed by similar methods.[31]

VFAs are most often analyzed by GC methods in these matrices.[30,64,65] Only recently has ICE been applied successfully to the analysis of these organic acids in landfill leachate.[56] Samples are usually stored at −18 °C directly after sampling. Sample preparation consists of centrifugation, filtration and removal of humin-like substances by adsorption onto polyvinylpyrrolidine cartridges. Two different ICE methods have been developed allowing for the determination of organic acids in the samples so prepared. These ICE methods analyze for a wider range of organic acids than the GC methods, hence giving a more complete picture of the organic acid composition in these matrices.

6 OTHER COMPLEMENTARY TECHNIQUES

A variety of other techniques beside ion chromatography are used to determine organic acids in various matrices. Only a few methods, which are either of specific interest or very commonly used, will be mentioned.

One of the most frequently used techniques is GC. Determination of VFAs, usually in wastewater but also in other matrices, is often accomplished by direct aqueous injection of samples after minimal sample preparation onto specialty GC columns.[30,64–66] Typically, only VFAs with a chain length from C_2 to C_5 are analyzed by this method. If the gas chromatograph is maintained properly these direct GC injections deliver fast results, which are utilized as operational parameters in wastewater treatment. Nevertheless, direct GC injection methods are only applicable to samples with high organic acid concentrations (milligrams per liter), since they lack the sensitivity necessary to measure low organic acid concentrations without further extensive sample preparation. In addition, acids such as formic acid or oxalic acid can not be measured by direct GC injection.

Other GC methods focus on the analysis of specific types of organic acid. These methods utilize more

complex sample preparations resulting in methods with high sensitivities and, hence, low DLs.[21–23,54,43–46] They usually consist of enrichment, derivatization and GC measurement. In fact, even aqueous derivatization may be applied which is the case when determining ketoacids in drinking water.[21–23] Organic acids determined by this type of GC method include monocarboxylic acids, ketoacids and dicarboxylic acids, often in rain or air matrices.

CE has gained considerable interest in environmental analysis. Advantages of this technique include very fast analysis times, high resolution and the necessity of using only small sample volumes. However, matrix-dependent changes in the migration times of compounds make peak identification difficult even when utilizing internal standards. More detailed information about CE can be found in various books.[67–69] CZE is the CE technique best suited for the analysis of small ions. One example of applying CZE to the analysis of environmental samples is the quantification of organic acids in single raindrops.[47,52]

ABBREVIATIONS AND ACRONYMS

CE	Capillary Electrophoresis

Capillary electrophoresis (CE) is an instrumental technique that employs narrow-bore (10–100 μm ID, internal diameter) capillaries under the influence of a high-gradient electric field to perform high-efficiency separations. Different working modes of CE have been described. Capillary zone electrophoresis (CZE) and micellar electrokinetic chromatography (MEKC) have become the most popular modes of CE in environmental applications. Other kinds of electrokinetic chromatography (EKC) and other modes of CE like capillary electrochromatography (CEC) have also been used.

CE techniques have been considered as a good alternative for analyzing pollutants because of their high performance and versatility related to selectivity and range of application. In addition, CE is a powerful tool in the field of chiral separations and it is considered one of the so-called clean analytical techniques. Although the main drawback of CE techniques in environmental analysis is their insufficient sensitivity for detecting trace-level pollutants, some procedures have been developed in order to overcome this problem.

1 INTRODUCTION

Chromatographic techniques are important tools for carrying out analysis of environmental pollutants. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) are the most common techniques used routinely and in complementary form in this type of analysis. Nevertheless, another instrumental technique has been developed as an interesting alternative to HPLC and GC techniques, that is, CE. The utilization of capillary tubes of ID generally ranging from 10 to 100 μm to achieve electrophoretic separations has enabled high efficiencies and an enormous resolution power to be obtained.[1,2]

Nowadays, the use of CE is one of the major trends in analytical chemistry and the number of publications has increased exponentially.[3] The limitations that GC techniques present for separating nonvolatile compounds (polar, acidic or basic, and thermally labile compounds) and the poor performance that sometimes characterizes HPLC techniques causing loss in resolution and sensitivity, have led to consideration of CE techniques as a good alternative for analyzing pollutants unsuitable for GC and affected by the poor efficiency of HPLC. In fact, they combine the high performance of GC techniques with the versatility of HPLC techniques with respect to selectivity and range of application.[4]

The importance of chirality in environmental control (enantiomers may have a different toxicity or one of them may not be toxic)[5] has given rise to the search for new and effective means of resolving enantiomeric mixtures.[6] The extent to which various chemicals are being applied in agriculture (many pesticides are produced as racemic mixtures and often only one enantiomer is biologically active) will soon require such potential ecological hazards to be monitored enantioselectively[7] and CE can be considered as a powerful separation tool in the field of chiral separations.[8] Aside from all other considerations mentioned here which show the great potential of CE, it can also be considered to be one of the so-called *clean* analytical techniques. This is due to the small volumes of mobile phase (electrolyte solution) and sample required to perform separations by this technique. This property confers great environmental interest on CE.

Despite the impressive potential for CE to achieve analytical separations, this technique has a major drawback: CE is not sensitive enough to detect trace-level environmental pollutants. Actually, government regulations require determination of lower and lower levels of pollutants in environmental samples so that the concentration

sensitivity of commercial CE instruments is far from ideal. In order to overcome this problem, some procedures to enhance CE sensitivity have been developed and are described below.

2 SEPARATION MODES FOR ENVIRONMENTAL ANALYSIS

Environmental pollutants are organic compounds from ionizable compounds, moderately hydrophobic compounds to highly hydrophobic compounds. Correspondingly, several working modes are needed, and some parameters must be taken into account such as electrolytic solution composition, capillary dimensions, capillary temperature, applied voltage and mode and time of injection. In order to optimize some of the above-mentioned parameters, some mathematical designs have been described.[9]

CZE and MEKC have become the most popular modes of CE in environmental applications.[10,11] Thus, their fundamentals will be described prior to outlining their potential for environmental analyses. Additionally, although less used in the environmental field, other kinds of EKC and other modes of CE like CEC, will be described.[11]

2.1 Capillary Zone Electrophoresis

2.1.1 Fundamentals

The most practical and simple working mode in CE is CZE. Separation by CZE is carried out in a capillary filled with a continuous background electrolyte (buffer).[12–14] The direction and migration velocity of analytes are determined by two phenomena, electroosmosis and electrophoresis.[15] Electroosmosis originates from ionized silanol groups on the inner wall of the fused-silica capillary which attract positively charged buffer ions to form an electrical double layer. The buffer ions in the mobile region of the double layer will migrate toward the cathode (negative pole) as soon as the voltage has been switched on and induce electroosmotic flow (EOF) of the entire liquid in the capillary. On the other hand, analytes are separated on the basis of their different electrophoretic migration velocities, which are related to their charge densities (mainly based on differences in solute size and charge at a given pH). Generally, the EOF will be higher than the electrophoretic migration velocity of most anionic analytes (which tend to migrate toward the positive pole). Consequently, both cations and anions will migrate in the same direction and can be separated in the same run, eluting initially the positively charged substances, the neutral ones (not separated), and finally the negatively charged solutes. This simplicity has contributed to the popularity of CZE.

CZE can only be used for the separation of ionic or ionizable compounds with low molecular weight and sufficient water solubility. These types of analyte are normally not very amenable to GC requiring, as a minimum, a sample derivatization which presents long sample preparation times and incomplete recoveries for many analyte derivatives. Therefore, the major competition for CZE techniques comes from the HPLC field. However, the higher efficiency of CZE and its different selectivity makes CZE complementary to HPLC. When comparing similar applications, CZE often requires a shorter analysis time and less effort in method development, owing to its huge separation power and flexibility in selectivity tuning. In addition, applications on CZE instruments are much more cost-effective than on HPLC, requiring inexpensive columns and a few milliliters of solutions.

The most important experimental parameter in CZE separations is the pH, except when completely ionized ions are separated. For this reason, some mathematical models have been developed for theoretical prediction of resolution as a function of the pH of the buffer.[16] Other less important parameters are choice of the buffer and its concentration and applied voltage. Unfortunately, many environmental pollutants are related isomers or have very close chemical structures, and therefore CZE often cannot provide sufficient resolution. To improve the separation, CZE has been used with additives such as organic solvents,[17] neutral cyclodextrins (CDs)[18] or neutral polymers.[19,20] Organic solvents are used as EOF and electrophoretic mobility modifiers to enable the separation of isomers or compounds with closed structures. The use of CDs in CZE has been recognized as a new kind of CZE named cyclodextrin-modified capillary zone electrophoresis (CDCZE). CDs are toroidal, with an axial void–apolar cavity and an outer hydrophilic surface, which form CD-inclusion complexes with certain molecules, based on the concordance of the solute molecular size with the cavity diameter of CD in addition to the hydrophobicity and chemistry.[21] Neutral CDs, despite migrating with the EOF, can form inclusion complexes with molecular compounds which have specific structural arrangements, modifying their electrophoretic mobilities and allowing the separation of pairs of enantiomers or improving multicomponent separation. On the other hand, neutral polymers interact with some analytes decreasing their electrophoretic mobilities and improving the separation.

Recently, cations like cetyltrimethylammonium bromide (CTAB), hexadimetrine bromide (HDB), and other alkylammonium salts have been used to produce a reversal of the EOF and to reduce analysis time of the anionic analytes which migrate in the same direction

as EOF. This principle is known as coelectroosmotic CE or reversed-polarity CE.[22–24]

2.1.2 *Applications to the Analysis of Compounds of Environmental Interest*

According to the principles described before, CZE can only be employed to analyze ionic or ionizable pollutants such as pesticides, plant growth regulators, phenols, amines, aromatic sulfonates, alkylsulfates, organometallic compounds and dyes. Table 1 summarizes the analytical conditions used to separate these compounds. These separations have for the most part been monitored by using UV (ultraviolet) absorbance detectors generally used in CE.

Pesticides (e.g. herbicides, fungicides, insecticides) include some compounds that persist in soils or aquatic environments and can be toxic to humans. Ionic and ionizable pesticides can be separated by CZE at the appropriate pH using acetate or phosphate buffers at pH between 3 and 8. In many cases, these compounds have been separated using only a buffer without additives. Examples are paraquat and diquat,[25] sulfonylureas,[26]

Table 1 Compounds of environmental interest analyzed by CZE

Compounds	Separation media	Detection	Application	Ref.
Pesticides	*Buffer*: phosphate (pH 3.5)	UV–254 nm	Paraquat and diquat	25
	Buffer: acetate (pH 5) *Additive*: acetonitrile	MS	Sulfonylureas	26
	Buffer: acetate (pH 4.8)	UV–200 nm	Phenoxy acids	27
	Buffer: borate (pH 6)	Indirect UV 200 nm	Alkylphosphonic acids	28
	Buffer: phosphate (pH 6) *Additive*: acetonitrile	UV–220 nm	Triazines	29
	Buffer: acetate (pH 4.8) *Additives*: heptakis(2,6-di-*o*-methyl)-β-CD and γ-CD	UV–200 nm		27
	Buffer: acetate (pH 4.45) *Additive*: TM-β-CD	UV–230 nm	Enantiomeric separation of optically active phenoxy acids	30
	Buffer: phosphate/borate (pH 5) *Additives*: β-CD, TM-β-CD alone or mixed	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 420$ nm		31
Plant growth regulators	*Buffer*: phosphate/borate (pH 7.5/8.1) *Additives*: α-CD, β-CD and γ-CD	Diode-array 196–210 nm	Three indole, three chlorophenoxyacetic and two naphthaleneacetic acids	32 33
Phenols	*Buffer*: phosphate (pH 6.9)	UV–210 nm	Chlorophenols	34
	Buffer: phosphate/borate (pH 7.7)	UV–215 nm	Dichlorophenol isomers	35
	Buffer: phosphate/borate (pH 9.8)	UV–210 nm	USEPA priority phenols	34
	Buffer: phosphate (pH 10.5)		Substituted phenols	36
	Buffer: phosphate/borate (pH 11) *Additives*: HDB and 2-propanol	UV–254 nm	Substituted phenols	22 23
Amines	*Buffer*: TRIS/acetate (pH 4.8)	UV–200 nm	Phenylenediamine isomers	37
	Buffer: acetate (pH 3.75)	UV–214 nm	Chloroaniline isomers	38
	Buffer: phosphate/citrate (pH 2) *Additives*: NaCl, methanol	Diode-array 190–263 nm	12 heterocyclic amines	11
Aromatic sulfonates	*Buffer*: borate (pH 8.3)	UV–214 nm	Eight aromatic sulfonates	39
	Buffer: borate (pH 9) *Additive*: acetonitrile		C_2–C_{12} linear alkylbenzene sulfonates	40
Alkylsulfates	*Buffer*: *p*-toluensulfonate *Additives*: methanol/ acetonitrile	Indirect UV 214 nm	C_9–C_{12} alkylsulfates	41

Table 1 (*continued*)

Compounds	Separation media	Detection	Application	Ref.
Organo-metallics	*Buffer*: pyridine (pH 2.5) *Additive*: CTAB	Indirect UV 254 nm	Alkyltin compounds	42
	Buffer: tartaric acid (pH 2.6) *Additives*: methanol, BTMA	Indirect UV 210 nm	Alkyltin compounds	43
	Buffer: borate (pH 8.24)	Diode-array 200–400 nm	Methylmercury	44
Dyes	*Buffer*: borate (pH 7.5) *Additive*: β-CD	UV–245 nm	Dyestuffs	45
	Buffer: TES/imidazole (pH 6.8) *Additives*: PEG, β-CD	UV–254 nm	Food colorants	46
	Buffer: BTP with HCl (pH 6.5) *Additives*: PEG and PVP	UV–214 nm	Nine synthetic organic dyes	20
	Buffer: citrate (pH 3.25) *Additives*: acetonitrile and CTAB	Diode-array 400–610 nm	Six reactive dyes	24

phenoxy acids[27] and alkylphosphonic acids.[28] In other cases, the CZE buffer contains additives such as organic solvents or CDs. Thus, prometon and prometryne (triazine herbicides) have been separated with a neutral buffer containing acetonitrile.[29] On the other hand, it is important to note that the addition of CDs to the separation buffer allows enantiomeric separation of several phenoxy acid herbicides.[27,30,31] Figure 1 shows the chiral separation of three optically active phenoxy acid herbicides in their six enantiomers by CZE using an acid buffer with tri-*o*-methyl-β-cyclodextrin (TM-β-CD) as additive.[30] They were separated from another nonchiral phenoxy acid at microgram per milliliter levels in an analysis time close to 12 min.

Plant growth regulators have been easily separated using a basic buffer with a cocktail of α-, β- and γ-CDs in order to enhance the selectivity.[32,33]

Phenols are important environmental pollutants owing to their high toxicity even at low concentrations. They are weak acids which can ionize in aqueous solutions and then can be analyzed easily by CZE using a buffer without additives. The pH chosen for the buffer depends on the types of compound, using phosphate or phosphate/borate buffers for neutral or basic pH values, respectively. Thus, the analysis of several chlorophenols requires a neutral pH,[34,35] although the eleven priority pollutant phenols listed by the USEPA (including chlorophenols, alkylphenols and nitrophenols)[34] and eight substituted phenols (different methyl-, dimethyl- and trimethylphenols)[36] have been separated using basic conditions. The 11 USEPA priority phenols can be completely resolved in less than 15 min by CZE (see Figure 2).[34] In this case, CZE provided better results than MEKC, because the analysis time was noticeably shorter compared with the 45 min obtained with MEKC,[47] or the 25 min typically required by HPLC.[48] Optimum conditions included a small buffer concentration and a basic pH, under which all phenols except one were ionized. Detection was performed with an on-column UV detector and good linearities ($r \geq 0.999$) were obtained for concentrations up to at least 50 ppm, with detection limits less than 1 ppm. On the other hand, the rapid analysis of substituted phenols has been achieved by using a buffer with a high pH value and HDB with propanol as additives.[22,23] In this method, the principle of coelectroosmotic CE, described above, was used. The application of CE techniques to the analysis of phenols has been reviewed.[49]

Amines such as heterocyclic amines are carcinogenic and mutagenic compounds that are found in cooked foods. Others like aromatic amines can contaminate water and soils. Based on their positive charge in acidic solution, several phenylenediamine isomers[37] and chloroaniline isomers[38] have been separated by CZE easily using only an acid buffer. On the other hand, the separation of 12 heterocyclic amines was optimized by orthogonal array design and the optimum conditions included the use of an acid buffer with NaCl and methanol as additives.[11]

Aromatic sulfonates are compounds separated by CZE using only basic buffers.[39] Alkylbenzene sulfonates are anionic surfactants widely used in detergent formulations, which have been separated by CZE using basic buffers with acetonitrile as additive.[40] The results show that CZE is more selective than MEKC for these compounds and the resulting analysis time is at least three times shorter compared with HPLC.[50]

Figure 1 Chiral separation of three optically active phenoxy acid herbicides and another nonchiral phenoxy acid by CDCZE. Conditions: separation media, 0.05 M acetate buffer (pH = 4.45) with 0.025 M TM-β-CD; capillary tube, 75 μm ID × 50 cm (to the detector); hydrodynamic injection, 5 s; applied voltage (current), 20 kV (41 μA); UV-detection at 230 nm; temperature, 30 °C. Peaks (analyte concentration, 1 μg mL^{-1}): (1) 2-(2,4,5-trichlorophenoxy)propionic acid, (2) 2-(2-methyl-4-chlorophenoxy)propionic acid, (3) 2-(2,4-dichlorophenoxy)propionic acid and (4) 2,4-dichlorophenoxyacetic acid. Separation of C_9–C_{12} sodium *alkylsulfates* was followed using indirect UV detection because there is no chromophore in the analyte molecules.[41]

Organometallic compounds such as organotin compounds have been analyzed by CZE employing an acid buffer and pyridine[42] or BTMA[43] to enable indirect UV detection. Methylmercury has been separated from an excess of cysteine at basic pH, using different reference materials.[44]

Dyes are colorants employed in the food and textile industries which frequently contaminate the aquatic environment. Some of them are anionic compounds suitable for analysis by CZE. Thus, seven food additive dyestuffs[45] and eleven permitted food colorants[46] have been separated using neutral buffers with CDs. Other synthetic dyes used as colorants for textiles have been separated using a neutral buffer with PEG and PVP as additives.[20] Reactive dyes have also been separated with an acid buffer and acetonitrile as additive.[24]

2.2 Micellar Electrokinetic Chromatography

2.2.1 Fundamentals

Even though CE was initially limited to the separation of charged compounds, the introduction of a micellar system in the separation buffer in 1984,[51] which resulted in the so-called MEKC, enabled CE to be applied to the separation of noncharged compounds.[52–56] In this technique, ionic surfactants are added to the CZE buffer at concentrations exceeding the critical micelle concentration (CMC) to form micelles which act as a pseudostationary phase.[57] The micelles are spherical aggregates whose hydrophobic groups are oriented toward the center of the micelle, with polar or charged groups along the sphere's surface. In this situation, neutral analytes are distributed between the buffer phase (which migrates with the velocity of the EOF) and the micellar phase (which moves at a velocity slower than EOF), resulting in separation. Because the micellar phase moves toward the detector, an elution window is created that

is bordered by a column void time (t_0, mobility of the EOF) and a micelle migration time (t_{MC}, mobility of the micelle). All the analytes must elute between these two limits, t_0 and t_{MC}, depending upon their partition between aqueous and micellar phases.[58] On the other hand, the migration behavior of ionizable solutes is more complicated because their electrophoretic mobilities have a great influence on the migration behavior and selectivity.[47]

Unfortunately, highly hydrophobic compounds tend completely to associate with the micelles and are not resolved because they coelute near t_{MC}. In order to enhance the usefulness of this technique, organic solvents (methanol, acetonitrile, tetrahydrofuran, or acetone),[59–61] and urea[62] were added to the buffer. In this case, the separation selectivity in MEKC can be controlled through the nature and concentration of the buffer and surfactant in the electrolyte solution and the nature and concentration of organic additives.[63] As an alternative to the addition of organic solvents (aggregation numbers and CMCs are affected by the addition of small amounts of organic modifier, and micelles are generally not stable in buffer with a high organic solvent content),[64,65] neutral CDs[66–71] are extensively used as modifiers in MEKC, giving rise to cyclodextrin-modified micellar electrokinetic chromatography (CDMEKC). In CDMEKC, neutral CDs will not interact with the micelle owing to its hydrophilic outside surface, but a hydrophobic solute is partitioned between the micelle (which migrates with the micellar velocity) and CD (which migrates with the EOF). Accordingly, the differential partition of the solute between CD-monomers and the micelles allows a separation.

The most widely used surfactants in MEKC have been those which are anionic in nature, especially sodium dodecyl sulfate (SDS) alone or with the additives previously described. Other possibilities, such as mixed micelles between SDS and neutral surfactants (Brij 35 (polyoxyethylenelauryl ether)[72] or PEG 400 monolaurate[73,74] or SDS homologs (sodium tetradecyl[52] or decyl[75] sulfates)) were tested to alter resolution and selectivity, but narrower retention windows or irreproducible times were obtained.

Bile salts, especially sodium cholate (SC) and sodium deoxycholate (SDC), have been considered promising pseudostationary phases in MEKC. They are important biological surfactants, based on a hydroxy-substituted steroid backbone, which form helical micelles with the hydrophobic portions of the monomer facing the aqueous solution while the hydrophilic portions turn inward. Thus, in some respects, bile salt micelles can be envisioned as ''inverted micelles''.[76,77] Their structure and aggregation behavior allow chiral recognition[78–80] and reduction of retention factor values with respect to those obtained with SDS.[81,82] In addition, bile salt micelles appear to tolerate high concentrations of organic solvents without drastic loss of efficiency or dramatic increase in analysis time.[65] These factors facilitate the analysis of hydrophobic compounds more easily than with SDS.

On the other hand, in situ charged micelles[83–86] are essentially anionic complexes formed between alkyl- or steroidal-glycoside surfactants and borate anions. They possess many unique and attractive features:

1. The surface charge density and the elution window increase with an increase in pH (upper 8) or borate concentration (25–400 mM).
2. Owing to the more balanced hydrophilic–lipophilic character than alkyl ionic surfactants, they are useful for separating hydrophobic compounds.
3. Some in situ charged micelles have chiral selectivity.[87]

Finally, although employed less in the analysis of environmental pollutants, other compounds have been used as micellar phases in MEKC:

1. different micelles such as alkyltrimethylammonium,[88] especially CTAB, disodium 5,12-bis-(dodecyloxymethyl)-4,7,10,13-(tetraosa)-1,16-hexadecanedisulfonate (DBTD)[89] and butyl acrylate–butyl methacrylate–methacrylic acid copolymers sodium salts (BBMA);[90]
2. oligomers with micelle-like structure such as sodium 10-undecylenate (SUA)[91] and sodium 10-undecylsulfate (SUS);[92]
3. macromolecules that are considered to mimic micelles such as dendrimers[93–95] and resorcarenes.[96]

MEKC systems compared with CZE are more complicated because of the additional experimental parameters that must be optimized[97] and because their electrolytic solutions are less stable than CZE buffer solutions owing to the effect of temperature on the distribution equilibria involved. In addition, the theoretical plate number in MEKC is not usually as high as could be achieved by CZE owing to the mass transfer resistance introduced by solute partitioning between the two phases. Consequently, sensitivity in MEKC is expected to be lower than in CZE.[98] Despite these drawbacks, MEKC has extended the enormous power of CZE to the separation of uncharged solutes and, moreover, it has demonstrated additional selectivity. This offers a good alternative for pollutants that are not amenable to CZE because they are electrically neutral solutes.

2.2.2 *Applications to the Analysis of Compounds of Environmental Interest*

MEKC is a mode of CE suitable to analyze neutral environmental pollutants such as mycotoxins, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorodibenzo-*p*-dioxins (PCDDs), or phthalates, and ionizable or ionic contaminants such as pesticides, phenols, dyes, amines, nitroaromatic compounds, organometallic compounds and sulfonates. The experimental conditions used to separate these compounds are grouped in Table 2. MEKC has been performed with several detection systems, such as UV absorbance, LIF, amperometric detection, and MS.

Mycotoxins are produced by fungi and they constitute a common class of environmental pollutants.[150] Conventional methods for mycotoxins analysis are thin-layer chromatography and HPLC;[151] however, these methods are very time-consuming and labor-intensive. These compounds, which cannot be analyzed by CZE, have been successfully resolved using MEKC. Three aflatoxins (mycotoxins that occur in a variety of foodstuffs intended for both livestock and human consumption) were separated by MEKC using SDC as surfactant in about 15 min.[65] The separation of 10 mycotoxins was optimized (fully resolved chromatograms in only 15 min) using two different MEKC systems, SDS with acetonitrile

Table 2 Compounds of environmental interest analyzed by MEKC

Compounds	Separation media	Detection	Application	Refs.
Mycotoxins	*Buffer*: phosphate/borate *Micelle*: SDC *Additive*: acetonitrile	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 450$ nm	Three aflatoxins	65
	Buffer: phosphate/borate (pH 9.3) *Micelle*: SDS or SDC *Additives*: acetonitrile or acetonitrile and γ-CD	UV–254 nm	Acidic and neutral mycotoxins (including four aflatoxins)	99
PAHs	*Buffer*: CHES (pH 10) *Micelle*: SDS *Additive*: propanol	UV–214 nm	Eight USEPA priority PAHs and 15 aromatic compounds	63
	Buffer: borate (pH 9) *Micelle*: SDS *Additives*: urea and γ-CD	UV–210/220/230/270 nm	The 16 USEPA priority PAHs and other homologs	66 70 100–102
	Buffer: borate (pH 9) *Micelle*: SDS *Additives*: urea, γ-CD and DMSO	UV–220/245 nm		103
	Buffer: borate (pH 9) *Micelle*: SDS *Additives*: urea and β-CD	UV–220 nm	Four USEPA priority PAHs and five aromatic compounds	67
	Buffer: borate (pH 7) *Micelle*: SDS *Additive*: γ-CD	UV–254 nm	Seven USEPA priority PAHs	69
	Buffer: phosphate/borate *Micelle*: SDS *Additives*: urea, γ-CD, (2-propanol)	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 400$ nm	Seven methyl-substituted benzo[*a*]pyrene isomers	71
	Buffer: borate (pH 9) *Micelle*: SDS *Additives*: urea, γ-CD and β-CD	UV–230 nm	10 hydroxylated homologs	104
	Buffer: phosphate/borate (pH 9) *Micelle*: SC or SDC *Additive*: methanol		Three USEPA priority PAHs	65
		LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 400$ nm	Four binaphthyl enantiomers	81
	Buffer: TRIS/phosphate *Micelle*: SDC *Additive*: DMF		Six USEPA priority PAHs	105

Table 2 (*continued*)

Compounds	Separation media	Detection	Application	Refs.
PAHs	*Buffer*: borate (pH 9.5) *Micelle*: CTAB *Additive*: acetonitrile	Diode-array 190–350 nm	Seven USEPA priority PAHs	106
	Buffer: borate (pH 10) *Micelle*: MEGA 10	UV–254 nm	Two USEPA priority PAHs and aromatic compounds	83
	Buffer: borate (pH 8.2) *Micelle*: SUA *Additive*: acetonitrile	UV–275 nm	11 USEPA priority PAHs	91
	Buffer: tetraborate *Micelle*: SUS *Additives*: acetonitrile or methanol	UV–214 nm	Six USEPA priority PAHs and six homologs	92
	Buffer: borate (pH 10.1) *Micelle*: SBD(X)-C_{12} *Additive*: methanol	UV–254 nm	Three USEPA priority PAHs and three homologs	95
	Micelle: resorcarene (pH 13.2) *Additives*: urea and acetonitrile	UV–260 nm	12 USEPA priority PAHs	96
	Buffer: borate (pH 9) *Micelle*: poly(D-SUV) *Additive*: γ-CD	UV–280 nm	Enantiomeric separation of naphthyl derivatives	107
PCDDs	*Buffer*: borate (pH 8/9) *Micelle*: SDS *Additives*: urea and γ-CD	UV–220 nm	TCDD isomers	66 108
PCBs	*Buffer*: borate (pH 8) *Micelle*: SDS *Additive*: urea and γ-CD	UV–220 nm	11 PCB congeners	66
	Buffer: CHES (pH 10) *Micelle*: SDS *Additives*: urea and γ-CD	UV–240 nm	14 PCB congeners	109
	Buffer: CHES (pH 10) *Micelle*: CTAB		Ten PCB congeners	110
	Buffer: CHES (pH 10) *Micelle*: SDS *Additives*: urea, γ-CD or γ-CD and β-CD	UV–235 nm	Enantiomeric separation of multicomponent mixtures of eight or nine chiral PCBs	111 112
	Buffer: CHES (pH 10) *Micelle*: SC *Additive*: urea		Enantiomeric separation of three PCBs	113
Phthalate esters	*Buffer*: phosphate/borate (pH 6/9) *Micelle*: SDS *Additive*: methanol	UV–210 nm	Phthalate esters (including priority USEPA phthalate esters)	114 115
Pesticides	*Buffer*: phosphate/borate (pH 5) *Micelle*: MEGA 10 *Additive*: TM-β-CD	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 420$ nm	Phenoxy acids	33
	Buffer: borate (pH 10) *Micelle*: MEGA 8			83
	Buffer: borate (pH 10) *Micelle*: OS or OM or OG or MEGA 9	UV–240 nm	Urea herbicides	84 85
	Buffer: borate (pH 7) *Micelle*: MEGA 10 *Additives*: PNA and acetonitrile	Indirect fluorimetry $\lambda_{ex} = 365$ nm $\lambda_{em} = 400$ nm	Lindane and herbisan	86

and γ-CD, or SDC with acetonitrile. Comparing the retention characteristics of sample and standard components under different MEKC conditions increased the reliability of peak identification.[99]

The separation of highly hydrophobic compounds and closely related compounds (PAHs, PCBs and PCDDs) is generally difficult by electrophoretic techniques, as explained before. In addition, it is often difficult to dissolve sufficient analyte in the aqueous micellar solution to enable detection by standard on-column UV detection. In an attempt to address these problems, several research groups have experimented with different separation procedures, which have been devoted to the separation of PAHs as shown in Table 2. PAHs which contain

at least two aromatic rings in their basic structure are of great environmental concern owing to their carcinogenicity. Multicomponent separations of PAHs have been carried out by MEKC using basic buffers with different surfactants to form the micellar phase such as SDS,[63,66,67,69–71,100–104] SC,[85] SDC[65,81,105] or CTAB.[106] The addition of organic modifiers to an electrophoretic medium is particularly advantageous for the analysis of hydrophobic analytes because they reduce the analytes' relative affinity for the micellar phase and increase solubility. CDs (CDMEKC) have been also employed to enhance the separation of highly hydrophobic compounds such as PAHs. The separation of a mixture of 20 PAHs by CDMEKC is illustrated in Figure 3. Finally, other authors have reported the separation of several PAHs using different pseudostationary phases:

1. in situ charged micelles such as MEGA 10;[83]
2. mimetic micelles such as oligomers (SUA[91] and SUS[92]), dendrimers (SBD(X)-C_{12})[95] or resorcarenes;[96]
3. combined polymerized chiral micelle with CD.[107]

PCBs and PCDDs are persistent environmental pollutants toxic to humans and animals. The separation of these compounds by MEKC is difficult owing to the low selectivity of the system in separating highly hydrophobic compounds. The addition of CDs and urea (increasing the solubility of hydrophobic compounds and CDs in aqueous media[63]) to the separation buffer in MEKC has enabled the separation of PCBs and PCDDs. CDMEKC using SDS with γ-CD and urea in the separation buffer has enabled successful separation of 11 trichlorobiphenyl isomers,[66] three pairs of trichlorodibenzo-*p*-dioxins,[66] different PCDD isomer pairs,[108] and 14 PCB congeners.[109] CTAB has been used as surfactant in CDMEKC to separate 10 PCB congeners.[110] In addition, CDMEKC with SDS has been employed to achieve the enantiomeric separation of 12 chiral PCBs each one in its two enantiomers using γ-CD[111] alone or mixed with β-CD[112] in the buffer. Multicomponent mixtures of nine[111] or eight[112] chiral PCBs were separated. Figure 4 shows the separation of the 18 enantiomers of a mixture of nine chiral PCBs, containing one octachlorinated biphenyl, in an analysis time close to 35 min.[111] Bile salts are alternate micellar systems for the separation of chiral compounds by MEKC and their use to separate three chiral PCBs, each one in its two enantiomers in less than 30 min has been described.[113]

Figure 3 Electropherogram corresponding to the separation of 20 PAHs by CDMEKC. Conditions: separation media, 0.14 M borate buffer (pH = 9.0) with 2.5 M urea, 0.10 M SDS, 0.042 M β-CD and 0.026 M γ-CD; capillary tube, 50 μm ID × 65 cm (50 cm to the detector); injection by pressure, 0.02 min at 20 mbar; applied voltage, 15 kV; UV–detection at 230 nm; temperature, 35 °C. Peaks (analyte concentration 100 μg mL^{-1}): (1) acenaphthene, (2) acenaphthylene, (3) naphthalene, (4) benzo(*g*,*h*,*i*)perylene, (5) fluorene, (6) phenanthrene, (7) pyrene, (8) chrysene, (9) perylene, (10) anthracene, (11) benzo(*e*)pyrene, (12) benzo(*a*)pyrene, (13) benzo(*a*)anthracene, (14) fluoranthene, (15) dibenzo(*a*,*h*)anthracene, (16) benzo(*k*)fluoranthene, (17) triphenylene, (18) benzo(*j*)fluoranthene, (19) benzo(*b*)fluoranthene, and (20) indeno(1,2,3-*cd*)pyrene. Figure 4 Electropherogram corresponding to the separation of a mixture of nine chiral PCBs by CDMEKC. Conditions: separation media, 0.10 M CHES buffer (pH = 10.0) with 2 M urea, 0.11 M SDS and 0.05 M γ-CD, capillary tube, 50 μm ID × 65 cm (50 cm to the detector), injection by pressure, 0.02 min at 20 mbar, applied voltage (current), 15 kV (56 μA), UV-detection at 235 nm, temperature, 45 °C. Peaks: DMF, each pair of enantiomers is identified by IUPAC number (according to Ballschmiter nomenclature; K. Ballschmitter, M. Zell, *Fresenius Z. Anal. Chem.*, **302**, 20–31 (1980)[152]); and (A) unknown peak. (Reproduced by permission of Chromatographia Vieweg-Publishing from M.L. Marina, I. Benito, J.C. Díez-Masa, M.J. González, *Chromatographia*, **42**, 269–272 (1996).[111])

Phthalates are widely used as plasticizers in industry, and can migrate from the plastics into the environment, so they are common contaminants in aquatic environments.[153] USEPA method 606 specifies analysis by GC with an electron capture detector, but appropriate pretreatment is necessary. The separation of six and ten phthalate esters, including some priority pollutants, was achieved by MEKC using SDS alone[114] or with methanol as additive[115] respectively. The use of SUA as a pseudostationary phase, in the presence of relatively high

amounts of organic modifier (acetonitrile), allows the separation and analysis of hydrophobic analytes such as phthalates.[91] The major disadvantage of this new phase lies in its laborious preparation (>2 days).

Pesticides have been widely studied by MEKC as shown in Table 2, since although they can be also separated by CZE, in some cases the separation can be enhanced by MEKC. Thus, multicomponent separation of different types of herbicides such as phenoxy acids, triazines, and phenylureas have been carried out by MEKC using mainly SDS[116–121,144] as anionic surfactant and other in situ charged micelles such as MEGA 8, MEGA 9 or MEGA 10.[33,83–86] Also, seven phenylurea herbicides have been successfully separated using cationic micelles such as TTAC with OTAC or DTAC.[88] On the other hand, enantiomeric separation of diniconazole and uniconazole,[122,123] and chiral separation of organochloride herbicides[124] have been performed by MEKC using SDS micelles with CDs as additives. Optical isomers of silvex herbicides have been separated using in situ charged Deoxy Big CHAP micelles.[87] Other chiral separations of phenoxy acid herbicides have been accomplished using neutral chiral surfactants such as OG, OM or NG.[125–127]

MEKC can also provide enhanced resolution of phenols in comparison with CZE. Thus, MEKC using SDS has been employed to separate substituted phenols,[51] chlorophenols,[53,128–130] and USEPA priority phenols.[47,131] A bile salt like SC has also been used as surfactant for a rapid separation of some priority phenols.[61] On the other hand, the addition of HP-β-CD in separation buffer with SDS enables the separation of 4-nonylphenol isomers and other alkylphenol homologs.[132] However, the separation mechanism of ionizable phenols by MEKC is complicated by the effect of the combined electrophoretic and chromatographic migration on separation. This explains the different elution orders shown in MEKC versus CZE. Although UV detection has been generally employed to determine phenols, a mixture of phenols has been analyzed by indirect fluorimetry[133] or amperometric detection.[134]

Finally, different types of compounds such as *dyes*,[135–139] *amines*,[140–142] *nitroaromatics*,[143–146] *aromatic sulfonates*[147] and *organometallics*[148,149] have been separated by MEKC using SDS micelles with or without additives such as organic solvents (acetonitrile, methanol, acetone), urea or CDs (see Table 2). The use of a bile salt like SDC has permitted the enantiomeric separation of tri aza aromatic ligand compounds of iron(II).[149] On the other hand, MEKC and CZE appear to be complementary in the analysis of *alkylbenzene sulfonates*.[40] MEKC with SDS is less selective than CZE for the separation of linear alkylbenzene sulfonates, although it appears to be much more selective than CZE for the separation of alkylbenzene sulfonate isomers.[40] However, MEKC with a nonionic surfactant such as Brij 35 instead of SDS improved the separation of these compounds with respect to CZE.[147]

2.3 Other Kinds of Electrokinetic Chromatography

One of the working modes most used in CE is EKC, which includes several techniques with the common feature that separations are based on the partitioning of the analytes between two phases which have different velocities relative to each other. One of the phases is a buffer solution (which migrates with the velocity of the EOF) and the other is a compound distributed homogeneously in the buffer solution, which is strongly electrophoretically retarded and acts as a pseudostationary phase. Micelles are the most used pseudostationary phase (MEKC is one kind of EKC), but other pseudostationary phases such as CD derivatives which have ionic groups, microemulsions, cationic or anionic surfactant monomers, or other alkyl–ionic compounds, which cannot be absolutely classed as micelles, have been successfully employed in EKC for the analysis of environmental compounds resulting in different modes of EKC.

Cyclodextrin electrokinetic chromatography (CDEKC) is a mode of EKC that can employ charged CD or mixtures of neutral and charged CD as the pseudostationary phase. In the first case, the distribution process between the analytes and the CD allows the separation by a host–guest interaction. As an example, cresol isomers have been successfully separated by using a negatively charged CD, carboxymethyl-β-cyclodextrin (CM-β-CD).[154] Using neutral and charged CD mixtures the separation was performed on the basis of differential partitioning of analytes between the two CDs moving relatively, neutral CD (which migrates with the EOF) and charged CD (which migrates with a given electrophoretic velocity and acts as a pseudostationary phase). Mixtures of methyl-β-cyclodextrin (M-β-CD) and sulfobutyl ether-β-cyclodextrin (SB-β-CD) have been used to provide efficient separation of PAH isomers.[155] The separation of these isomers using mixtures of α-CD or β-CD with CM-β-CD was also successful.[156] Thus, the 16 PAHs listed by USEPA as priority pollutants have been separated with the system formed by M-β-CD and SB-β-CD[157,158] in less than 20 min.

In microemulsion electrokinetic chromatography (MEEKC), the pseudostationary phase is a microemulsion, that is, an aggregate with a similar structure to that of a micelle, except that it has a core of a minute droplet of oil. Microemulsions are prepared by mixing oil (hydrocarbon), water, surfactant, and co-surfactant (medium alkyl-chain alcohol) in the appropriate proportions. This technique has been studied in comparison

with MEKC using phenol derivatives[159] and phenylurea and chlorsulfuron herbicides as model mixtures (see Figure 5).[73] Results have shown that with MEEKC it is very easy to extend the retention window through an increase in the surfactant concentration, and moreover MEEKC provides different selectivities from MEKC.

Finally, in hydrophobic interaction electrokinetic chromatography (HIEKC), the pseudostationary phase can be formed by cationic or anionic surfactant monomers, or other alkyl–ionic compounds in hydro-organic solutions with high concentrations of organic solvent (≥40%). Under these conditions, micelles are not formed because of the high concentration of organic solvent. The separation mechanism is attributed to the hydrophobic interaction between a monomolecular pseudostationary phase and neutral analytes. A series of alkyl aryl ketone homologs[160] has been successfully separated, in less than 6 min, by HIEKC using phosphate buffer at pH 7.0 with SDS or at pH 2.8 with CTAB as anionic or cationic surfactant, respectively, in 50% acetonitrile. Several mixtures of PAH homologs have been well resolved using a basic buffer (about pH 9) in 40–50% acetonitrile and with tetrahexylammonium perchlorate (five homologs),[161] or tetraheptylammonium bromide (16 homologs)[162] or sodium dioctylsulfosuccinate (23 homologs).[163]

Figure 5 Separation of seven herbicides by MEEKC. Conditions: separation media, 0.0124 M dihydrogenophosphate/0.0038 M borate buffer (pH = 7.0) with 0.070 M *n*-octane, 0.800 M *n*-butanol and 0.050 M SDS; capillary tube, 50 μm ID × 75 cm (55 cm to the detector); hydrodynamic injection, 10 cm × 5–20 s; applied voltage 24 kV; UV-detection at 254 nm; temperature, 30 °C. Peaks: (1) DMF, (2) chlorsulfuron, (3) fenuron, (4) monuron, (5) fluometuron, (6) chloroturon, (7) dinuron, (8) linuron, (10) impurity in *o*-diphenylbenzene and (11) *o*-diphenylbenzene. 2.4 Capillary Electrochromatography

The combination of CZE and HPLC, called CEC, is one of the newest working modes in CE.[164–166] In CEC, the separation of uncharged analytes is based on partitioning between a mobile phase (buffer which migrates with the velocity of the EOF) and a stationary phase (HPLC material which is static at all times). The stationary phase can be either coating the inner wall of a capillary (open tubular column, OTC) or packing the inner diameter of the capillary (packed capillary column, PCC). The advantage of using EOF[164] as the driving force is an increased column efficiency because of the flat-flow profile, and moreover, in the case of PCCs the ability to use smaller particles than those used in HPLC (particle diameters as small as 1.5 μm) because EOF is not limited by the column back pressure that results from the passage of a mobile phase through a packed bed, the flow being limited in this case only by the voltage applied. The separation of charged analytes is also possible in CEC, but in this case, the analyte migration velocity will be determined by the partition between the two phases described previously and its electrophoretic mobility. Although two kinds of column can be used (OTC or PCC), most applications have employed PCCs with an ID of less than 100 μm, and these have been commercialized, while OTCs are still in the developmental stage. Generally, PAHs[167–170] have been used as standards to evaluate OTCs. Some compounds such as PAHs,[171–173] benzene derivatives,[174] nitrotoluenes and biphenyls[175] have been utilized to evaluate PCCs. Figure 6 shows an electrochromatogram of 16 USEPA priority PAHs with a PCC of 75 μm ID and 3 μm octadecylsilica (C_{18}) particles using a buffer with a high percentage of organic solvent.[176] Attempts have been made to separate the same mixture of PAHs in HIEKC[162] and MEKC,[66] but with poorer results. A linear gradient elution in CEC was used for the separation of 16 PAHs showing a better performance than in isocratic elution.[177]

It should be emphasized that CEC is still not widely applied owing to the difficulty in manufacturing and operating the PCCs.

3 ANALYSIS OF POLLUTANTS IN ENVIRONMENTAL SAMPLES

Most environmental applications in CE are restricted to demonstrations of high-resolution separations with standards of specific pollutants and only a few refer to the determination of pollutants in environmental samples.

Figure 6 Electrochromatogram corresponding to a mixture of 16 USEPA priority PAHs. Conditions: separation media, 0.004 M borate buffer with 80% acetonitrile, capillary tube, 75 μm ID × 43 cm (33 cm packed length), electrokinetic injection, 5 s × 5 kV, applied voltage, 15 kV, LIF-detection ($\lambda_{exc} = 257$ nm, $\lambda_{em} = 400$ nm). Peaks (analyte concentration 10^{-6}–10^{-8} M): (1) naphthalene, (2) acenaphthylene, (3) acenaphthene, (4) fluorene, (5) phenanthrene, (6) anthracene, (7) fluoranthene, (8) pyrene, (9) benzo(*a*)anthracene, (10) chrysene, (11) benzo(*b*)fluoranthene, (12) benzo(*k*)fluoranthene, (13) benzo(*a*)pyrene, (14) dibenzo-(*a*,*h*)anthracene, (15) benzo(*g*,*h*,*i*)perylene and (16) indeno(1,2,3-*cd*)pyrene. (Reproduced by permission of American Chemical Society. Copyright (1995) from C. Yan, R. Dadoo, H. Zhao, R.M. Zare, *Anal. Chem.*, **67**, 2026–2029.[176])

There are two main reasons for this. First, CE commercial instruments have been introduced only relatively recently and are not yet in widespread use in environmental analytical laboratories. Second, the sensitivity obtained for the analysis of pollutants by CE has not been adequate for trace analysis. Unfortunately, the injection volumes that can be tolerated in CE without decreasing separation performance, are typically a few nanoliters only. Therefore, although commercial CE instruments equipped with UV absorbance detectors are able to detect quantities as low as several hundred femtograms,[6] very poor sensitivity is obtained as expressed in sample concentration terms (several hundred parts per billion or above 10^{-6} M), which are generally at least three orders of magnitude above levels of pollutants in environmental samples (low parts per billion to parts per trillion level). Because the detection ability of commercial CE instruments is far from ideal and they are not sensitive enough to determine compounds in environmental samples, improvements needed to be made to detection systems or preconcentration procedures.

3.1 Sensitivity Enhancement Procedures

Several approaches have been developed to improve the limit of detection (LOD) for CE instruments,[178] such as extending the optical path length of the capillaries, using highly sensitive detection systems, and employing several strategies for the preconcentration of samples, namely, solid-phase extraction (SPE), field-amplified sample stacking (FASS), or isotachophoresis (ITP).

3.1.1 Improved Capillary Geometry and Detector Cell Design

Unfortunately, the detection system that can be used in CE, without decreasing the separation performance, is an on-column detection, which implies that the optical path length for detection is limited by the ID of the capillary column. Some authors have extended the optical path length by using Z-shaped flow cells[179] which improve the LOD by a factor of 20–60, or bubble cells[84,180] which allow a multiplying of sensitivity usually by a factor of 3–5.

3.1.2 Alternative Detection Systems

Fluorescence detection can provide LODs several orders lower than UV absorbance. In applications of environmental interest the excitation of molecules is done with different lasers in order to achieve very high sensitivities of LIF. Thus, the laser most used in LIF for pollutants analysis is the He–Cd laser ($\lambda_{ex} = 325\,nm$). It is employed (see Table 2) for the determination of hydrophobic compounds with native fluorescence such as aflatoxins[65] or PAHs[65,71,81,95,105,157,181–183] in which LODs are 10^{-9}–10^{-11} M. However, most environmental pollutants are not intrinsically fluorescent, like some phenoxy acids herbicides[33,127] which are analyzed by LIF after a derivatization with a fluorophore (e.g. 7-aminonaphthalene-1,3-disulfonic acid (ANDSA)) achieving a LOD around a few parts per billion. The Ar ion laser ($\lambda_{ex} = 257\,nm$) has been employed to analyze 16 USEPA priority PAHs.[127,157] A semiconductor laser[105,184] has also been employed for detection of PAHs obtaining worse sensitivity (LOD 10^{-8} M) than with a He–Cd laser. Finally, another alternative for nonfluorescent analytes is the use of indirect LIF detection. This detection is the result of the decreased signal from a fluorescing reagent present in the running buffer, which is caused by the displacement of the reagent with nonfluorescing analytes. Indirect LIF detection was employed in the separation of six aromatic compounds,[185] two neutral herbicides,[86] 11 USEPA priority phenols[186] and a mixture of phenols (phenol, 1-chlorophenol and cresol isomers).[133] LODs for these compounds were in the 10^{-6}–10^{-7} M range.

MS is one of the most powerful detection methods for obtaining structural information on separated analytes. Recently, capillary electrophoresis/mass spectrometry (CE/MS) has been recognized as a promising technique for analysis of mixtures of pollutants. Thus, sulfonylurea herbicides have been analyzed by CZE using ion spray MS.[26] Moreover, aromatic amines have been analyzed by MEKC using an electrospray-chemical ionization interface.[140] However, some problems still exist in CE/MS. This detector has relatively poor concentration sensitivity. The use of nonvolatile buffers is generally avoided (composition of buffer must be chosen previously). On the other hand, the coupling of MEKC with MS is difficult owing to the presence of high concentrations of micelles in the running buffer, which can cause low ionization efficiency. Nevertheless, current research is rapidly changing this situation by developing new CE/MS interfaces, and novel pseudostationary phases.

Amperometric detection is advantageous because LOD should not increase with a decrease in the ID of the capillary column as occurs with UV detection. However, this type of detection has been scarcely used in CE, particularly in the analysis of environmental pollutants, owing to its difficult manipulation and to the limited number of pollutants with electroactive character. Actually, amperometric detection has been used for the analysis of phenols[134,187] and chlorophenols[188] reaching a LOD close to 10^{-8} M.

3.1.3 Preconcentration by Solid-phase Extraction

Liquid–liquid extraction (LLE) and SPE are the most common methods for liquid sample enrichment. LLE is a successful method but with recognized disadvantages: it is laborious, time consuming and subject to problems such as the emulsification of the samples during extraction and the disposal of large volumes of toxic solvents. Thus, trace enrichment of environmental samples in CE analysis is preferably performed via SPE (see Table 3), providing concentration factors of 10–10^6, and being especially effective for aqueous samples. In off-line SPE, large-volume samples are passed through a small cartridge packed with sorbent. Analytes are trapped by the sorbent and then eluted with a small volume of a suitable solvent. An alternative technique based on the SPE principle but with a piece of sorbent membrane disk to replace the SPE cartridge has been reported.[189] Because the sorbent disk has a larger contacting area than a SPE cartridge, larger flow rates are permitted, and therefore the extraction for large-volume (1 L or more) samples can be performed in much shorter times than with a SPE cartridge. Nevertheless, with the off-line preconcentration technique, the sample is not introduced directly into the capillary, requiring major handling of the samples and analysis time. For this reason, an on-line coupled SPE/CZE has been described[29,190] using a reversed-phase coated capillary column to perform SPE preconcentration before CZE separation. However, owing to the small amount of reversed-phase coating on the inner wall of the capillary, the breakthrough volumes and the capacity, and hence the enrichment factors, are rather limited (10–35-fold). This is why on-line SPE is used with a short plug of

Table 3 Experimental conditions for the analysis of pollutants in environmental samples by CE

Compounds	CE mode	Sample preconcentration	Separation media	Capillary length[a] × ID (mm)	Injection	Detection	Application	Ref.
Aflatoxins	MEKC	Off-line SPE	*Buffer*: 50 mM phosphate/6 mM borate *Micelle*: 50 mM SDC *Additive*: 10% acetonitrile	350 × 0.025	Electromigration	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 450$ nm	Determination of aflatoxins in Indiana corn meal extract spiked with 16 ppm	181
Amines	CZE	Off-line SPE	*Buffer*: 50 mM phosphate (pH 2.35) *Additive*: 1,3-diaminopropane	600 × 0.050	–	UV–280 nm	Determination of anilines in groundwater and soil extracts from industrial plant	192
Dyes	MEKC	Off-line SPE	*Buffer*: 50 mM borate (pH 8.35) *Micelle*: 100 mM SC *Additive*: 10% acetone	500 × 0.050	–	UV–214 nm	Determination of dyes in soil extracts spiked with 3 ppm	138
Pesticides	CZE	FASS	*Buffer*: 50 mM acetate (pH 4.8) *Additive*: 4 mM α-CD	760 × 0.050	–	UV–200 nm	Chiral separation of herbicides in a Rhine river water sample spiked with 5 ppb of phenoxy acid	193
		ITP	*Leading buffer*: 10 mM citric acid (pH 6.08), 0.2 mg mL^{-1} MHEC *Terminating buffer*: 9.8 mM citric acid (pH 6.08) 0.15 mg mL^{-1} PEG	ITP column: 80 × 0.085 CZE column: 250 × 0.025	–	UV–310 nm	Determination of paraquat and diquat in water samples	194
		Off-line SPE	*Buffer*: 40 mM borate (pH 8.5)	500 × 0.075	–	UV–214 nm	Monitoring of herbicides in water sources	195

Pesticides	CZE	–	*Buffer*: 100 mM borate (pH 9.6) *Additive*: 10% methanol	720 × 0.050	Hydrodynamic	UV–240 nm	Determination of glyphosate in human serum treated (acid precipitation and centrifugation)	196

	CDEKC	–	*Buffer*: 50 mM borate (pH 9.0) *Additives*: 25 mM SB-β-CD and 20 mM β-CD	500 × 0.050	Hydrodynamic	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 370$ nm	Determination of the 16 USEPA priority PAHs in a contaminated soil extract	157

Phenols	CZE	–	*Buffer*: 40 mM borate (pH 10)	560 × 0.050	Hydrodynamic	UV–230 nm	Determination of pentachloro-phenol in 100 mL of tap water sample spiked with 0.5 ppb	180
		–	*Buffer*: 15 mM borate (pH 9.9) with 1 mM fluorescein	450 × 0.020	Electromigration	Indirect fluorimetry	Determination of the 11 USEPA priority phenols from industrial wastewater	186
		–	*Buffer*: 20 mM CHES (pH 10.1)	625 × 0.050	Electromigration	Amperometric (+1.5 V)	Determination of the 11 USEPA priority phenols from industrial wastewater	187
		LLE	*Buffer*: 15 mM borate/45 mM phosphate (pH 8)	350 × 0.025	Electromigration	Amperometric (+1.4 V)	Determination of chlorophenols from industrial wastewater	188
Sulfonates	MEKC	Off-line SPE	*Buffer*: 50 mM borate *Micelle*: 100 mM SDS	700 × 0.075	–	UV–230 nm	Determination of naphthalene sulfonates in spiked river water	205
	CZE	Off-line SPE	*Buffer*: borate (pH 8.75)	800 × 0.075	–	LIF $\lambda_{ex} = 325$ nm $\lambda_{em} = 370$ nm	Identification and quantitation of two trisulfonates and amino-trisulfonates in Elbe river samples	205

[a] Capillary length to the detection. MHEC, methylhydroxyethylcellulose.

a reversed-phase material (particles) which is packed at the beginning of the separation capillary.[191] These capillaries have a somewhat higher capacity and will show higher breakthrough volumes and enrichments (up to 100-fold). However, the main disadvantage is that these capillaries are only available from a limited number of suppliers, and are much more expensive (at least 30 times) than the simple fused-silica capillaries commonly used in CE. In addition, an environmental sample can almost never be directly introduced because the system could suffer plugging and severe contamination. Therefore, the sample must be cleaned or extracted and should not contain a high percentage of organic solvent.

3.1.4 On-column Preconcentration by Field-amplified Sample Stacking

FASS occurs when the injected sample has a lower ionic strength than the running buffer. Then, an analyte ion dissolved in the sample matrix will experience locally an increased field strength and will migrate with a higher velocity. When the analyte reaches the boundary between the sample matrix zone and the running buffer, it will slow down again and stack into a zone much shorter than the original sample zone, thus the analyte has been preconcentrated or focused on-column. Cationic compounds are focused at the front of the sample zone and anionic compounds at the back of the sample zone.[193]

In the simplest form of FASS, a plug of sample (dissolved in diluted buffer or in water) with a very short length compared to the total length of the capillary, is introduced hydrodynamically into the capillary. In this case, LODs can be improved by a factor of 10. However, when attempting to inject a larger volume of sample, a laminar flow occurs and destacks the stacked analyte ion.[206] Fortunately, Burgi and Chien[207] provided a simple method for removing the relatively large sample matrix zone during or after the enrichment step, but before the CZE separation started. This can be accomplished by pumping out the matrix zone, using the EOF. For anionic analytes, this involves field polarity reversion after the capillary is filled with the sample, but for cationic analytes, this demands a reversed EOF. Therefore, the enrichment factor attainable by field amplification can also benefit from the EOF and LODs can then be improved by a factor of 200. The same technique can also be performed by electrokinetic injection with LODs improved by a factor of 1000. However the reproducibility is poor.

FASS can be also used in MEKC. For ionic analytes, the procedure is the same as that for CZE. However, for neutral analytes the procedure involves dissolving them in a micellar solution with a low concentration just above the CMC. Then, the micelles will be stacked up under applied voltage and will cause stacking of neutral analytes.

3.1.5 On-line Preconcentration by Isotachophoresis

ITP is a working mode in CE which is performed in a discontinuous buffer system.[208] The analyte ions of an injected sample migrate between a leading buffer having the highest mobility and a terminating buffer having the lowest mobility. When voltage is applied, the analyte ions will be focused and migrate as consecutive zones, according to their mobility, between the leading and terminating buffers.[209] From the point of view of trace analysis, on-line coupling of ITP and CZE is very attractive[193,210] because it reduces the LOD by a factor of 10^3–10^4. However, this technique has seldom been employed in environmental analysis (see Table 3) because it requires complicated instrumentation.

ITP can be also performed before CZE separation as an ITP-like state realized only for a limited period of time (transient-ITP preconcentration step).[193,210] Transient-ITP is possible when the sample contains an excess of a matrix ion with higher electrophoretic mobility than analytes, and at the same time, the CZE electrolyte has a lower mobility than analytes. In this case, the matrix ion can act as a leading buffer and the CZE electrolyte as a terminating buffer. This technique can be used in commercial CE instruments by carefully selecting the CZE electrolyte to form an ITP buffer system and it could reduce the LOD by a factor as high as 200 when analytes migrate just behind the matrix ion. However, as in ITP, there are some disadvantages:

1. It might be difficult occasionally to find a suitable combination of leading and terminating buffers.
2. The migration times of analytes in unknown samples may be hard to predict.
3. Irreproducibility of EOF will give bad enrichment performance.

Finally, the enrichment procedures described above (FASS and ITP) can be problematic in some environmental samples where matrix components may also be concentrated; significant background matrix may degrade separation and mask the analytes of interest. Another drawback is that concentration enhancement can be reduced, eliminated or even reversed when the sample has a relatively high electrolyte content, because the sample zone may broaden, decreasing the separation efficiency and then the concentration sensitivity may decrease significantly. To resolve these problems, some authors employ a sample preconcentration technique like SPE coupled with FASS[143] or with ITP/CZE[194] for separating some pollutants. Such combination allows

the minimum detectable concentration of analytes to be decreased to low parts per billion or even parts per trillion levels without using sophisticated and expensive detection systems.

3.2 Analysis of Pollutants in Environmental Samples

CE has been employed to analyze pollutants in environmental samples and environmental matrices spiked with standards. Table 3 shows experimental conditions employed to analyze these compounds arranged alphabetically.

MEKC has been employed to determine hydrophobic compounds such as *aflatoxins*. High-speed separation of four aflatoxins in less than 30 s was optimized[181] and a bile salt such as SDC was used with acetonitrile as additive. This separation coupled with an on-column LIF detector allows LODs in the range 0.05–0.9 fmol for underivatized aflatoxins. This method was applied to the analysis of a spiked (16 ppm) corn meal extract obtained by SPE.[181] *Amines* from groundwater and soil samples preconcentrated by off-line SPE have been easily analyzed by CZE based on their positive charge in acidic solution.[192]

Dyes and *pesticides* can be separated by both CZE and MEKC. In the case of seven *monosulfonated dyes*[138] from spiked water and soil samples, MEKC was selected for its better selectivity. On the other hand, the potential and drawbacks of CE for the monitoring of pesticides water pollution have been discussed.[195] CZE has been employed primarily[193–199] (seven of ten works in Table 3), although MEKC has also been used.[200–202] UV detection was used in all cases (Table 3) and different sample treatments (off-line SPE, FASS and ITP) were employed. Figure 7 shows the electropherogram corresponding to a Rhine river water sample spiked with 5 ppb of four herbicides, two of them chiral, by using CZE and a derivative of β-CD as chiral selector in the separation buffer (sample volume 20 mL).[193] In Figure 8, the versatility and efficiency of MEKC in the separation of 11 herbicides from distilled water are shown. In the same electropherogram, ionic herbicides and various nonionized herbicides are separated in a short analysis time.[195]

Other pollutants such as *nitroaromatic* and *organometallic* compounds have been determined by MEKC in heavily contaminated soil samples and in water samples, respectively. Because the concentrations of nitroaromatic compounds were relatively high (soil from military zones), the analysis was accomplished by MEKC with UV detection without preconcentration.[203] The possibility of determining organolead and organotin compounds in other environmental samples such as drainage and tap waters has also been demonstrated.[204] Figure 9 presents

Figure 7 Electropherogram corresponding to a Rhine river water sample (sample volume 20 mL) spiked with 5 ppb of four herbicides (two chiral) by CDCZE and using preconcentration by off-line SPE (C_{18} disks) coupled with FASS. Peaks: (1) 2-(2-methyl-4-chlorophenoxy) propionic acid, (2) 2-methyl-4-chlorophenoxyacetic acid, (3) 2-(2,4-dichlorophenoxy) propionic acid, and (4) 2,4-dichlorophenoxyacetic acid. Conditions: separation media, 0.03 M acetate buffer (pH = 4.8) with 20 g L^{-1} heptakis-(2,6-di-*o*-methyl)-β-CD, capillary tube, 50 µm ID × 76 cm, applied voltage, 30 kV, UV-detection at 200 nm, temperature, 30 °C. (Reproduced by permission of Elsevier Science Publishers. Copyright (1993) from M.W.F. Nielen, *Trends Anal. Chem.*, **12**, 345–356.[193])

Figure 8 Separation of 11 herbicides from distilled water by MEKC. Peaks (analyte concentration, 1–2 mg L^{-1}): (1) tribenuron, (2) chlorsulfuron, (3) metsulfuron, (4) paraquat, (5) simazine, (6) atrazine, (7) linuron, (8) terbuthylazine, (9) alachlor, (10) metolachlor, (11) trifluralin. Conditions: separation media, 0.030 M borate buffer (pH 8.0) with 0.030 M SDS; capillary tube, 75 µm ID × 50 cm, applied voltage, 25 kV, UV-detection at 214 nm, temperature, 30 °C. (Reproduced by permission of Elsevier Science Publishers. Copyright (1996) from G. Dinelli, A. Vicari, P. Catizone, *J. Chromatogr. A*, **733**, 337–347.[195])

Figure 9 Electropherogram of four organometallic compounds in the extract from 1 L rain water by MEKC. Peaks: (1) methanol, (2) trimethyltin (49.8 ng mL^{-1}), (3) trimethyllead (18.4 ng mL^{-1}), (4) unknown, (5) triethyllead (50.0 ng mL^{-1}), (6) tributyltin (28.8 ng mL^{-1}), (7) NaDDC (sodium diethyldithiocarbamate) + unknown. Conditions: separation media, 0.030 M dihydrogenphosphate/0.015 M borate buffer (pH 7.65) with 0.050 M SDS, capillary tube, 50 µm ID × 60 cm (50 cm to the detector), hydrodynamic injection, 10 cm × 10–20 s, applied voltage, 20 kV, UV-detection at 200 nm. (Reproduced by permission of Marcel Dekker Inc from K. Li, S.F.Y. Li, H.K. Lee, *J. Liq. Chromatogr.*, **18**, 1325–1347 (1995).[204])

the separation by MEKC of the most common organolead and organotin compounds (trimethyltin, trimethyllead, triethyllead and tributyltin) in the extracts from 1 L of rain water samples after disk SPE extraction. In addition, CDMEKC was also applied to separate two organolead and two organoselenium compounds from water samples using LLE for sample enrichment.[148]

PAHs have been analyzed in contaminated soil samples by different kinds of EKC and detection systems. Thus, several PAHs were determined in an extract of creosote-contaminated soil by MEKC with a bile salt and UV detection at 214 nm.[61] Quantitation of seven PAHs in soil samples contaminated with a mixture of standard PAHs and machine oil was carried out by MEKC with SDS and diode-array detection[106] and 16 USEPA priority PAHs contained in an extract obtained by supercritical fluid extraction (SFE) of a contaminated soil sample were determined by CDEKC using a mixture of charged and neutral CDs and LIF detection ($\lambda_{ex} = 325$ nm).[157]

CZE has been used to determine several *chlorophenols* in different water samples.[180,188] The fact that phenols respond to a sensitive detection method such as electrochemical detection has allowed determination of seven chlorophenol isomers and three neutral phenols in industrial wastewater by CZE with on-column electrochemical detection (see Figure 10).[188] LODs in the picomole range were achieved by thermostating the separation capillary and no interference from the impurities present in industrial wastewater samples were observed, using only a simple LLE with chloroform–diethyl ether. Therefore, the use of an electrochemical detector provides excellent sensitivity and selectivity without derivatization. Thus, the separation of 11 USEPA priority phenols by CZE with on-column amperometric detection has been successfully applied to the analysis of industrial wastewaters.[187] In order to minimize the large electrophoretic currents, which seriously interfere with amperometric detection, CHES was used as the running buffer because of its

Figure 10 Electropherogram of an industrial wastewater sample obtained by CZE with electrochemical detection. Peaks: (1) phenol, (2) 2-chlorophenol (concentration, 50 ng mL^{-1}), (3) 4-chlorophenol, (4) 2,4-dichlorophenol, (5) 2,6-dichlorophenol, (6) *o*-phenylphenol, (7) catechol, (8) 2,4,6-trichlorophenol, (9) 2,3,4,6-tetrachlorophenol, (10) 4,5,6-trichloroguiacol, and (11) pentachlorophenol. Conditions: separation media, 0.045 M dihydrogenphosphate/0.015 M borate buffer (pH 8.0), capillary tube, 25 µm ID × 65 cm (30 cm to the detector), electrokinetic injection, 20 kV × 30 s, applied voltage, 20 kV; amperometric detection using a carbon fiber at +1.4 V versus SCE (standard calomel electrode); temperature, 20–25 °C. (Reproduced by permission of Elsevier Science Publishers. Copyright (1990) from C.D. Gaitonde, P. Pathak, *J. Chromatogr.*, **514**, 389–393.[188])

zwitterionic nature. The analysis of similar samples was achieved by CZE with indirect laser-induced fluorescence detection.[186] This detection technique involves the addition of a noninteracting and fluorescing ion to the running buffer to create a constant fluorescence background and when a charged analyte is present, it displaces the fluorescing ion of the same charge owing to local charge neutrality, resulting in a decreased background signal even though the analyte does not absorb or fluoresce.

Finally, other pollutants separated by CE were *sulfonates*, which were analyzed by MEKC with UV detection in spiked river samples.[205] or by CZE with LIF detection in unspiked river samples.[205]

In general, Table 3 shows that the analysis of pollutants in environmental samples can be resolved by two means: (i) sample preconcentration with off-line SPE (principally with a C_{18} disk), or (ii) use of detectors with enough sensitivity (LIF or amperometric detection). In both cases, it is possible to obtain a LOD of about 10^{-9} M which is adequate for the determination of pollutants in several environmental matrices or samples.

4 CONCLUSIONS

CE is a newly developed separation technique, which has demonstrated its enormous capability and potential for separating ionic and neutral solutes owing to its simplicity and high efficiency. The first option for analyzing ionic or ionizable compounds by CE is CZE with or without additives to increase separation selectivity. When this selectivity is poor or the compounds to be analyzed are not ionizable, separation by CE should be achieved by means of MEKC with or without additives to improve separation resolution. Finally, other kinds of EKC or CEC can be used to enhance the separation or decrease the analysis time.

CE is very suitable for those analytes that are not amenable to GC (polar and acid or basic pollutants, e.g. modern pesticides in aqueous samples) or when existing HPLC methods do not offer sufficient separation power. Many efficient and rapid CE separations of standards, including compounds of environmental interest, have been described. Despite the excellent prospects for CE, the analysis of pollutants in environmental samples where these compounds are at trace level (governmental regulations require determination of lower and lower levels of pollutants in environmental samples) requires the use of enrichment procedures or highly sensitivity detectors. Off-line extraction, preconcentration techniques and special injection methods are being developed. A simple clean-up, followed by a large-volume injection and a high-efficiency separation in a CE system, should be adequate to fulfill the requirements of real-life environmental applications. Several research groups are developing their own highly sensitive detectors such as LIF, which has become popular mainly because of its capability to provide extremely high sensitivity (10^{-12} M). Unfortunately, this type of detector is not generally applicable in environmental analysis. Many interesting pollutants cannot be derivatized using any of the few fluorescence labels which match the particular laser lines. Other sensitive detection systems, such as laser-induced resonance energy transfer,[211] chemiluminescence[212] and inductively coupled plasma MS[213–215] are being developed. With respect to MS which is one of the most powerful detection systems, current research is devoted to developing new CE/MS interfaces in order to increase the possibility of CE/MS being able to solve problems in environmental analysis.

Concern for the environment is not limited to ecological aspects, but encompasses matter such as the origin and the effects of pollutant discharges, the evaluation of environmental programs, quality control and quality assurance related to analytical precedures, and the analysis of the content of environmental matrices – both inorganic and organic – in order to control and evaluate environmental pollution. Thus, it is right to say that analytical chemistry has an important role to play in environmental analysis.

A large number of analytical methods are used in environmental analysis. Some are widely used in environmental programs, and are reference/standard/official methods for the analysis of a great variety of compounds.

However, there is no single universal procedure that can be applied to the analysis of any chemical species in any environmental matrix, and for any in situ/remote measurement.

Electrochemical (EC) methods are widely used to investigate environmentally significant compounds, both organic and inorganic. EC research covers all important branches of environmental analysis, such as in situ/remote measurements, flow systems, combined applications with a separation technique, (bio)sensors for selective analysis, and monitoring and control procedures.

This article discusses the application of these EC methods to the study of organic compounds occurring in environmental water and waste samples.

1 INTRODUCTION

Modern EC methods are applicable to a very large number of organic compounds of great importance, not only in environmental monitoring but in many other fields.[1]

Most applications of chemical analysis to environmental protection involve trace determinations; consequently, highly sensitive methods that offer good selectivity, precision, and accuracy are needed. Other desirable characteristics are easy sample pretreatment, quick analysis, easy automatization of the method, the availability of a portable device for field measurements, low cost of instrumentation and analysis.[2]

Assignments given to environmental analysis include: the quantitative and qualitative control of pollutant emissions in the environment; the elucidation of the path of the emitted pollutant from its source to its interaction with humans; the monitoring/study of the conversion and transformation of pollutants as well as their natural reactions; and the discovery and elucidation of processes for the prevention of the emissions or processes for their neutralization. Unfortunately, it is impossible to monitor the content, distribution and fate of all chemical substances present in the environment, whether man-made or naturally occurring.

Polarography was one of the first techniques for monitoring some anthropogenic pollutants at the trace level in real environmental samples, in particular for heavy metals. Nowadays, EC methods have to compete with other methods – the whole analytical procedure, from problem definition to data evaluation, must be taken into account when choosing the right determination method. Economic aspects are also very important, and include the cost of instrumentation, the qualification and number of operators, sample requirements (such as the sampling method, necessity and manner of storage), and the possibilities and difficulties of the process automatization;[3] of increasing importance for

environmental monitoring is quality assurance and quality control.

A large number of important organic environmental compounds are electrochemically active, either directly or indirectly. In most cases, the sensitivity is adequate for organic environmental analysis; the use of stripping techniques, especially adsorptive stripping analysis for organic compounds, increases this sensitivity. Selectivity is limited by several factors, such as the number of compounds that are active in a same range, the overlapping of signals, and surface alterations of the electrodes. Using chemical reactions it is sometimes possible to achieve experimental situations to solve most problems without using special separation techniques. However, in many organic analyses the variety of compounds is much larger, and similar compounds are only badly or not distinguished at all by their EC properties. For these more complex problems, the use of EC sensors after high-performance liquid chromatography (HPLC) or other separation technique offers an attractive solution. Although EC methods have a moderate equipment cost, the whole analytical process must be priced for a particular sample. Experienced staff are also necessary for the accurate analysis of complex environmental samples when using modern methods and instrumentation for EC trace analysis.

In voltammetry, a continuous changing potential is applied and the current that flows is continuously recorded; the term 'polarography' is reserved for voltammetric methods in which an electrode with a renewed surface is used. The most-used techniques for analytical purposes are cyclic, differential pulse, and square wave voltammetry. Potentiometry involves the measurement of the potential of a working electrode (WE) as a constant current is passed through an EC cell; sensors based on MOSFET (metal oxide semiconductor field effect transistor) semiconductors is a developing field in potentiometric analysis. Coulometry is based on the deposition (or conversion to another oxidation state) of an analyte on an electrode at a constant potential.

One of the main applications of electroanalysis is in trace determination of organic pollutants of interest; the needs of environmental analysis include the use of flow systems, mainly on-line flow systems coupled to separation methods with electrochemical detection (ED) for the analysis of complex environmental samples.

Chromatography is the most important and popular separation technique, but a sensitive detector is needed for the separated compounds. For organic analysis, the most common EC measuring technique in chromatography/flowing liquids is amperometry, i.e. the measurement at a constant electrode potential. Amperometric detectors were introduced by Kissinger et al. in the early 1970s for oxidative ED of catecholamines at carbon electrodes. Phenomena at an interface between a solution and an electrode can be exploited for potentiometric, coulometric, and voltammetric detectors. Potentiometric detectors are based on the measurement of the electromotive force under zero current conditions. With voltammetric detectors, the current is measured as a function of an applied potential. Amperometric, pulsed amperometric, and scanning voltammetric detectors are all classified as voltammetric detectors. In coulometric detectors an electrode reaction efficiency of practically 100% is obtained.[4]

Separation techniques can also be used for preconcentration and enhancement of sensitivity, and thus lower detection limits can be obtained. Although stripping techniques involve a preconcentration step, the separation is usually a secondary effect as the aim of stripping is to improve the sensitivity of the determination.[5]

The most important EC methods applied to environmental analysis are based on the measurement of signals due to phenomena at an interface between an electrode and a solution. However, there are some problems associated to this superficial interaction. The sensitivity of electrode interfaces in stripping methods, with respect to the adsorption of interferences or surface alterations, is the main source of problems for their application to real environmental samples. This is particularly true in the case of incomplete destruction of organic matrix components. Selectivity is limited in voltammetry because of overlapping voltammetric signals. One of the most critical aspects of the routine analysis of complex environmental samples is the stability and reproducibility of the WE surface. The use of renewable mercury electrodes avoids this problem, but its toxicity is an increasing matter of concern; solid electrodes with stable and reproducible surfaces are a very interesting field where very important progress is being made.

The application of EC (bio)sensors is a possibility, due to several characteristics, such as intrinsic specifity, fast analysis, and minimal requeriments for sample treatment. However, widespread application of EC (bio)sensors for environmental purposes is remains limited by the low stability of (bio)sensors and their high detection limits.[6] EC (bio)sensors can be useful for field monitoring, to provide enough information for the routine testing and screening of samples. In this way they can be used to establish an unmanned measuring system for the continuous monitoring of the environment at selected sites, or used as a component of a portable instrument for incorporation in flow systems.[7]

In situ measurement offers several advantages. The operations connected with the collection, transport and storage of samples are eliminated, and so the cost of the global process is lower, and the delay and

error incurred in such operations can be avoided. The measurements are carried out in real time and the pollutant is analyzed in its own environment. The results are obtained quickly, and consequently the problem can be solved promptly. Remote EC sensors for monitoring organic pollutants are a very interesting field, and advances in EC technology now enable the use of modified electrodes, ultramicroelectrodes, the design of highly selective recognition layers, sensor arrays, and development in the areas of microfabrication, flow detectors, and compact, low-powered, user-friendly instrumentation.[8]

2 SAMPLE PREPARATION

The use of analytical procedures applied to environmental analysis involves a succession of steps, including: sampling and storage of environmental samples; the collection of treatments that must be carried out on the sample for quantification; and final determination and presentation of results. Several operations can be considered of general application to most procedures. After sampling, samples are filtered, usually through a 0.45 μm filter, and stored in the dark at 2–4 °C. After treatment, and when a chromatographic system is used, evaporation of the solvent prior to chromatographic analysis is carried out, in order to reduce the sample to an appropiate volume for injection. Most analytical papers dealing with environmental applications include an exact procedure for the sample treatment.

In environmental analysis, the analyzed species are seldom accessible directly to the detector. Treatment procedures include digestion, extraction and separation steps, which can add considerable uncertainly to the overall results. Matrix influences also have to be evaluated. The inestability of the analyte in the sample must be considered. Due to the high ionic content of some samples it is advisable to determine several species directly, as in seawater. Sometimes it is necessary to form a derivative which can be determined electrochemically.

Usually, UV (ultraviolet) digestion by sulphuric acid/hydrogen peroxide or by microwave digestion is used. In the analysis of organic pollutants, when water samples are too complex and/or the analytes very diluted, preliminary preparation prior to the analysis is needed. Traces of organic pollutants must be extracted from aqueous media and concentrated, and other components which can also be co-extracted and co-concentrated, and which may interfere in the analysis, must be removed from the matrix. The most usual methods for extraction and concentration of organic pollutants are liquid–liquid extraction (LLE) and solid-phase extraction (SPE).

The LLE technique has been used for many years due to its simplicity and good results. If a nonpolar solvent is chosen as the extractant, the addition of a supporting electrolyte is necessary to ensure a solution of sufficient conductivity before EC determination. The popularity of SPE has increased because of the reduced use of organic solvents. Micro-LLE is always an attractive solution. In the field of SPE, new sorbents are being developed in order to improve the selectivity in this preliminary step, to enable subsequent steps of removing interferents to be eliminated or simplified.[9]

Even though separation techniques are somehow always undesirable, because they will always increase the amount of labor and cost of the analysis, in many cases their application is necessary to reduce interference and/or to increase the sensitivity of the method by preconcentrating the analyte.[5] Environmental analysis includes the use of flow systems coupled to separation methods, such as chromatography, with ED for the analysis of complex environmental samples. As chromatography is only a way to separate compounds from each other, is necessary to use a detector which is sensitive to the separated compound. For organic analysis, the most common EC measuring technique in chromatography is amperometry, though some others detectors, such as coulometric, potentiometric, pulsed amperometric and scanning voltammetric detectors are also used.

The combination of capillary electrophoresis and electrochemistry is a developing field within EC research, and has been used for the analysis of catecholamines, carbohydrates, amino acids, chlorophenols and explosive compounds.[10] ED appears to be promising for analysis of compounds with well-defined redox behavior. Capillary electrophoresis has a high resolution, is suitable for ionic/polar and apolar compounds, but has a low loading capacity, in the range of few nanoliters; this last characteristic is not a disadvantage for very sensitive techniques. Table 1 gives several examples of the preparation/treatment/extraction procedures used with environmental samples.

3 ENVIRONMENTAL APPLICATIONS

The number of papers related to EC methods applied to environmental analysis is increasing. Different matrices, compounds and specific strategies of analysis have been reviewed to provide a general view of the applications of these methods. Analytical techniques for the determination of chemical species in natural water, drinking water and wastewater have been sumarized, including EC methods.[39]

In general, the sensitivity required in the determination is not a restriction when EC methods are

Table 1 Examples of preparation/treatment/extraction procedures used with environmental samples prior to EC analysis

Analyte	Sample	Previous treatment	Extraction/treatment for measurement	Ref.
Organic explosives (Organic nitro compounds)	groundwater	stored in the dark at 2–4 °C; exposition to daylight for differents periods of time for monitoring degradation processes	direct injection into HPLC system	11
	well/surface water	(a) stored in the dark at 4 °C; (b) extracted inmediately	(a) LLE with methylene chloride; (b) SPE	12
	groundwater	addition of sodium azide; stored in the dark at 4 °C	LLE with dichloromethane pH 9, retention of the neutral/basic fraction; LLE with dichloromethane pH 2, retention of the acidic fraction	13
Aromatic amines	drinking water	without filtration	on-line preconcentration/ extraction system by two precolumns	14
	groundwater	refrigerated at 5 °C; filtered through a 0.22 μm filter disk	LC with precolumn sample preconcentration	15
Aromatic hydrocarbons	tap water, motor oil		tetrahydrofuran was used to dilute water samples or to extract oil samples Ce(IV) is added to oxidize aromatic hydrocarbons to quinones	16
	ground, surface, river, rain, drinking water	addition of 2-propanol; filtered through a 0.45 μm filter	SPE; evaporation of the solvent and the residue diluted with methanol–water for HPLC analysis	17
PCBs (TCB)	wastewater	filtration and dissolution of the insoluble material in methanol		18
(Aroclors®)	industrial water effluent	drying agent	LLE with a water-immiscible solvent, mechanical shaking for 20 min	19
Phenols	seawater	filtered, adjusted to pH 2 and stored at 4 °C	SPE and elution with acetonitrile	20
	seawater	filtered through a 0.45 μm filter, adjusted to pH 2 and frozen at −20 °C	SPE	21
	river, tap water	filtered through a 0.45 μm filter, adjusted to pH 2 and stored at 4 °C	solid-phase disk extraction	22
	river water		on-line SPE	23
(Total phenols)	industrial wastewater	stored at 4 °C	SPE	24
(Catecol, phenol)	wastewater	filtered through a membrane filter, adjusted to pH 5	SPE	25
(Phenol, *o*-cresol)	tap water, wastewater		comparision between drect injection, LLE and on/off line SPE	26
Pesticides (Amitrole)	drinking and groundwater	water samples (5 mL) concentrated to 0.5 mL under a nitrogen stream; filtered through a 0.5 μm membrane filter		27
(Phenylurea herbicides)	tap, mineral and spring water	stored in the dark at 2–4 °C	SPE by Sep-Pak cartridges (C_{18}); elution with methanol	28

Table 1 (*continued*)

Analyte	Sample	Previous treatment	Extraction/Treatment for measurement	Ref.
(Phenylurea and chlorotriazine herbicides)	river, estuarine and coastal seawater	(a) on-line analysis: sample filtered through a glass microfiber (b) off-line analysis: sample filtered through a glass microfiber, porosity 0.7 μm	(a) precolumn packed with styren–divinylbenzene copolymer; elution by an acetonitrile–water gradient via a LC pump (b) SPE (C_{18}); elution with acetonitrile; evaporation to dryness and dissolved in acetonitrile–water (20 : 80)	29
Surfactants (Poly(ethylene glycols))	river water		LLE with ethyl acetate and chloroform	30
(Nonionic surfactants)	river water		LLE with ethyl acetate	31
	surface water and wastewater		reaction with molybdophosphoric acid for complexation	32
(Linear alkylbenzene sulfonates)	tap water and sewage	complete evaporation to dryness of the sample; dissolution with methanol and evaporation of the solvent	nitration with fuming nitric acid for 15 min at 30 °C; evaporation of nitric acid and dissolution of the residue with Britton–Robinson buffer solution of pH 12	33
Organometallics (Tributyltin)	seawater	preconcentration by a cation exchanger; elution with HCl–methanol	LLE with dichloromethane	34
(Methyl-, ethyl-, phenylmercury)	river water	addition of sodium pyrrolidenedithiocarbamate for complexation reaction with the mercury compounds	SPE and elution with methanol; evaporation of the solvent to dryness; reconstitution of the residue prior to injection into the chromatographic system	35
(Alkyllead compounds)	seawater	stored in the dark at 4 °C; addition of sodium diethylthiocarbamate	double extraction with 20 + 10 mL hexane; re-extraction for carbamate complexes to an acid aqueous solution	36
Miscellaneous (9,10-Anthraquinone)	natural water, industrial samples		Continuous steam distillation/extraction device	37
(Phthalate esters)	wastewater		LLE with hexane (two or three extractions are required); alkaline hydrolysis of the esters	38

LC, liquid chromatography; PCBs, polychlorinated biphenyls; TCB, trichlorobiphenyl.

applied to the analysis of organic pollutants. Detection limits obtained with these methods compare well with those obtained by other methods; several papers describe comparative studies between ED and other detectors.

Problems associated with possible interferences are, sometimes, particular when EC methods are used. It is known that selectivity of some EC applications is poor. Many organic pollutants have similar molecular structures. Therefore, the use of an unspecific electrode without a previous separation step results in the overlapping of the redox responses of similar compounds when their mixtures are analyzed. It is difficult to find a specific reaction or specific sustrate electrode for each organic compound.

Most EC processes used in environmental analysis take place on an electrode surface, so reproducibility and stability of the active surfaces is an important consideration. Unfortunately, these characteristics are not easy to achieve. As a result of the problems associated with the use of mercury electrodes, most research deals with new and more sensitive combinations of EC detectors and separation techniques, specific (bio)sensors for organic pollutants, and the stabilization of electrode surfaces.

Trace organic contaminants in surface water have been considered.[40] The methods described in literature or used in laboratories often derive from those used for drinking water, with additional treatments. There is a general trend to develop LC methods, due to their advantages over gas chromatography (GC) for a large

number of environmental pollutants. EC methods for the determination of anilines and chloroanilines are described, with detection limits below $0.1\,\mu g\,L^{-1}$.

As most applications use a separation step combined with ED, there are reviews that discuss the advantages and limitations of combining separation technique and voltammetry,[5] as well as reviews that describe the EC detectors used for LC and capillary electrophoresis.[4] Different types of detectors are considered, and much effort is directed at overcoming the difficulties of using combined techniques to achieve selective determinations.

Biosensors offer many possibilities for the analysis of organic pollutants. Despite the problems associated with biosensors, their attributes, such as selectivity, in situ/remote measurements, and minimal requirements for sample analysis are very important, and research in this field is increasing. Although amperometric and potentiometric transducers are used,[41] an electrical transducer and a potentiostat can also be used for detection. Most reports refer to amperometric biosensors, because they offer higher sensitivity and selectivity. Although potentiometric devices are not used as much, they still make an important contribution. For example, an enzyme (cholinesterase) potentiometric biosensor can be used for preliminary testing of the total pollution of domestic and industrial discharges.[42]

The most used biosensors are tyrosinase based and peroxidase based. Environmental organic pollutants are either enzyme substrates or enzyme inhibitor, for both types of biosensors.[43] Whereas thioureas, mercaptoethanol, hydroxylamine, methylisothiocyanate, and cyanide are detected with a peroxidase biosensor, carbamates are detected with a tyrosinase biosensor. The use of cholinesterase-based biosensors has also been described.[44] These biosensors are applied to the analysis of organophosphate and carbamate pesticides; acettylcholinesterase and butyrylcholinesterase are the enzymes used for the analysis of pesticides in real environmental samples. Potentiometric or amperometric transducers can be used for the analysis of these pesticides. Most potentiometric enzimatic biosensors are based on the immobilization of an appropriate esterase and measurement of the pH change which is produced; a glass electrode or a pH-sensitive ion-sensitive field effect transistor (ISFET) is usually used as the internal detector for the pH change.[45] Different amperometric transducers are employed. They use the reduction of oxygen, or the oxidation of hydrogen peroxide or thiocholine. In general, amperometric detection reaches lower detection limits than potentiometric detection.[46]

EC immunoassays are based on modifications of enzyme immunoassays (EIAs) and the enzyme activities are determined potentiometrically or amperometrically. Some EC immunosensors have been described, including one for the analysis of PCBs using a conducting polymer-based immunosensor.[47]

Among specific strategies, a review on developments and applications of screen-printed EC sensors and their applications to environmental analysis can be found.[48] Several analytes have been studied in environmental samples, and the research focuses on obtaining portable devices and the ability of performing environmental analysis away from a laboratory. Amperometric biosensors have been applied to hydrazines, hydroquinona, phenols and pesticides. Two interesting alternatives are the use of remote sensors and submersible probes for organic analyltes, by appropriate modification of the surface of the electrode and deposition of chemical recognition layers.[8]

Phenolic compounds belong to a very important group of organic pollutants. The EC literature on these compounds is wide, and the methods developed for their determination include EC detectors coupled to separation techniques, amperometric (bio)sensors, and remote measurements. Methodologies for the determination of phenolic compounds in some water types have been reviewed including ED, amperometric biosensors, and emerging techniques.[49] Applications of EC methods to the determination of other groups of organic pollutants in environment have been also described, such as organoarsenic and organotin compounds,[50,51] surfactants,[52,53] ethylenediaminetetraacetic acid (EDTA)/diethylenetriaminepentaacetic acid (DTPA).[54]

4 ENVIRONMENTAL REGULATIONS AND METHODS

In spite of the proven applicability of EC methods for organic analysis, there are few examples of EC methods being used as reference and/or official methods for the organic analysis of environmental samples.

Most current official analytical methods are based on LLE followed by GC using different detectors, such as electron capture and mass spectrometry (MS). However, there is a general trend to change these procedures to SPE followed by HPLC.[49]

The methods for organic chemical analysis of municipal and industrial wastewater, used by the United States Environmental Protection Agency (USEPA), include HPLC with an ED procedure for the determination of benzidines at a glassy carbon electrode, or equivalent. An LLE procedure is used in the sequence chloroform–acid–chloroform; the final chloroform extract is exchanged to methanol while it is being concentrated using a rotary evaporator for introduction into the HPLC system. Detection limits of $0.08–0.13\,\mu g\,L^{-1}$ are reported.[55]

Polarography has been proposed as an official German standard method for nitrilotriacetic acid determination in water, wastewater, and sludge.[1] The German ESB (environmental specimen banking) programme includes the regular determination of a wide variety of organic and inorganic species; electroanalytical methods and other analytical techniques are used to carry out these determinations.[3]

European Community Directive 76/464/ECC lists organic compounds to be eliminated from discharges. The drinking water standard methods are described in Directive 79/869/ECC. These methods are chemical group-specific analytical parameters, and nowdays are insufficient for the analysis of pollutants in water samples of different nature and origin. For example, nonionic surfactants are determined from potentiometric measurement after precipitation with bismuth. Many of the newly developed methods have been derived from those used for drinking water. So, a selective preconcentration technique has been described for the analysis of anilines and chloroanilines by cation exchangers coupled to a oxidative ED; these highly toxic substances are included in Directive 76/464/ECC, and their determination is possible thanks to the selectivity of the procedure. River water samples are analized, and detection limits below $0.1\,\mu g\,L^{-1}$ are reported.[40]

5 METHOD DEVELOPMENT

5.1 Nitrated Organic Explosives Components

Nitrated organic compounds have been widely used as munitions components; they have been produced in large quantities, and have to be regulated by environmental agencies.

There are several reasons for the great interest in the determination of organic explosives. First, their inherent toxicity; moreover, some of the biotransformation products, mainly aminoaromatic compounds, are known or suspected cancerogens or mutagens. Second, the localization of these explosives; surface and groundwater are generally contaminated by explosives in the vicinity of former ammunition plants, and decommissioning of military bases for other uses must be accompanied by verification that all pollution has been removed. Table 2 shows the application of EC methods to the analysis of nitrated organic explosives in environmental samples.

An HPLC method with UV and ED is described for monitoring the degradation of organic explosives. Amino and phenolic compounds are determined by oxidative ED (+1.1 V) at a glassy carbon electrode, whereas UV detection is used for nitro compounds. The samples (groundwater taken near a former ammunition plant) is injected directly in the HPLC system. To achieve the degradation of the explosives, samples are exposed to daylight for different periods of time.[11] Figure 1 shows the effect of light exposure on water samples for differents periods of time.

The use of hanging mercury drop electrode (HMDE) and the mercury film electrode (MFE) have been described for the reductive ED of organic explosives.[56,12] Well and surface water samples are collected, and two different extraction techniques are used, LLE and SPE. The extract is injected in an HPLC system with reductive ED (−1.0 V) at a MFE.

A glassy carbon WE in an HPLC system with ED allows the application of both reductive and oxidative detection.

Table 2 Environmental analysis of nitrated organic explosives by EC methods

Analyte	Sample	Detection limit	Comments about the method	Ref.
Organic explosives (Organic nitro compounds)	groundwater	–	monitoring degradation processes, HPLC with amperometric detection of amino derivatives, glassy carbon WE at +1.0 V	11
	well/surface water	–	HPLC with reductive amperometric detection at −1.0 V, gold–mercury thin-film WE	12
	groundwater	[a] 4–25 $\mu g\,L^{-1}$	HPLC with reductive/oxidative detection, 0.6–1.2 V and −(0.6–1.2) V, glassy carbon WE	13
	groundwater		electrokinetic capillary electrophoresis with amperometric detection at −0.7 V	
		(a) 70–110 $\mu g\,L^{-1}$	(a) gold WE	
		(b) 140–300 $\mu g\,L^{-1}$	(b) silver-on-gold WE	10
(Trinitrotoluene)	river/drinking water		EC sensor for remote continuous monitoring of 2,4-trinitrotoluene	
	groundwater		Square-wave voltammetry at a carbon fiber electrode	57

[a] Value for oxidative mode; for reductive mode, 5–10 times higher detection limits are obtained.

Figure 1 Representative chromatograms of directly injected water samples: (a) UV detection, sample not exposed; (b) UV detection, sample exposed for 80 days; (c) ED, sample not exposed; (d) ED, sample exposed for 80 days. (Reproduced by permission of Springer-Verlag from ref. 11.)

Nitroaromatics, nitramines, aminoaromatics and nitrophenols were determined in groundwater samples from the surroundings of a former ammunition plant, and the results compared with those obtained by UV detection. A two-step LLE procedure is used: dichloromethane at pH 9 to obtain the neutral/basic fraction, and at pH 2 for the acidic fraction.[13]

Electrokinetic capillary electrophoresis with amperometric detection has been used for the determination of organic explosives.[10] ED is carried out by a silver-on-gold electrode at −0.7 V. A groundwater sample obtained in the vicinity of the remediation site is used as sample. Detection limits in the range 70–110 $\mu g\,L^{-1}$ were found for all explosives, lower in all cases than with UV detection. Excellent agreement was found between the results obtained by capillary electrophoresis with amperometric detection and the standard USEPA method.

A remote EC sensor reported by Wang et al.[57] allows the continous monitoring of the explosive 2,4,6-trinitrotoluene. Square wave voltammetry as the EC

technique, and a submersible carbon-fiber as the WE are used. The electrode is connected to a 50 ft shielded cable. The response is very selective due to the low detection potential for the explosive. Low mg L^{-1} detection limits are obtained for untreated river water, groundwater and drinking water spiked with 2,4,6-trinitrotoluene.[57]

5.2 Aromatic Amines

Amines are present in the environment at the trace level. They enter the environment from a variety of sources, such as industrial discharges, from pesticide degradation, or from bacterial conversion of azo compounds into the precursor amines.

Aromatic amines are included in the EPA list of priority pollutants. The EEC directives give a concentration limit of 1 μg L^{-1} for all aromatic amines in drinking water, and 0.5 μg L^{-1} for the concentration of individual compounds. Table 3 shows the application of EC methods to the analysis of aromatic amines in environmental samples.

LC with ED has been described for the analysis of aromatic amines as these compounds are easily oxidized. Different aqueous environmental samples have been analyzed using LC or HPLC,[15,58] and a potential in the range 0.4–1.0 V is usually required together with previous sample preconcentration.

Cyclic voltammetry and hydrodynamic voltammetry can be used to study the voltammetric characteristics of these compounds. Aromatic diamines have a significantly lower oxidation potential than the monoamines, so the applied potential can be used for the individual analysis of aromatic mono- or di-amines.[59]

The UV detection limits at 235 nm and for ED at 0.9 V are always below the regulatory limits. Although UV detection can be used alone, ED provides complementary information for identification of the analytes.[14]

The use of DNA recognition layers has enabled the development of a DNA-modified electrode for detection of toxic aromatic amines.[60] It can be used as a screening tool for these compounds.

5.3 Other Nitrogen-containing Compounds

An amperometric sensor for flow injection analysis (FIA) of hydrazines has been developed; the electrode is a Nafion–ruthenium(III) modified glassy carbon electrode for the study of electroxidation of hydrazine compounds.[61] EC oxidation of hydrazine catalyzed by 4-hydroxy-2,2,6,6-tetramethyl-piperminyloxy at a glassy carbon electrode has also been applied to waste and river water.[62]

For hydrazines, a DNA-coated carbon paste electrode has been used as a sensitive biosensor for the detection of hydrazine compounds, by means of potentiometric stripping analysis. DNA immobilization is carried out at 1.7 V; for measurement, a stripping current of 8 μA is used.[63] Sensors for field monitoring studies are always an important trend in environmental analysis. A remote EC sensor for field monitoring has been described for hydrazine, based on a catalytic film of 3,4-dihydroxybenzaldehyde. The electrode is coupled to a shielded cable for remote operation.[64]

Capillary electrophoresis with ED has been used for the analysis of hydroxylamine. An ultramicro palladium particle modified carbon fiber electrode was employed and applied to the analysis of river and wastewater.[65]

Polarography of nitrilotriacetic acid complexed with Bi(III) is widely applied to verify the pollution of waters.

Table 3 Environmental analysis of aromatic amines and hydrazines by EC methods

Analyte	Sample	Detection limit	Comments about the method	Ref.
Aniline derivatives	drinking water	10–20 μg L^{-1}	LC with amperometric detection	14
Aromatic amines	river, groundwater	0.1–60 × 10^{-7} M	potentiometric stripping analysis at a DNA-modified carbon paste electrode	60
	groundwater	25 ng L^{-1}	LC with amperometric detection at a carbon paste or glassy carbon electrode	15
	tap water		HPLC with amperometric detection	59
	groundwater	<0.1 μg L^{-1}	HPLC with ED	58
Hydrazynes	river, groundwater	<2 mg L^{-1}	potentiometric stripping analysis at a DNA-modified carbon paste electrode	63
	river, lake, groundwater		electrocatalytically modified electrode based on a film of 3,4-dihydroxybenzaldehyde for remote monitoring	64
	river, wastewater	1 × 10^{-6} M	voltammetry determination based on catalytic reaction at a glassy carbon electrode	62
	drinking, river water	1 × 10^{-7} M	amperometric sensor based on a Nafion–ruthenium(III) modified glassy carbon electrode	61

Table 4 Environmental analysis of hydroxylamines, nitrilotriacetic acid and aromatic hydrocarbons by EC methods

Analyte	Sample	Detection limit	Comments about the method	Ref.
Hydroxylamine	river, wastewater	5×10^{-8} M	capillary electrophoresis with ED at a paladium particle modified carbon fiber microdisk array electrode	65
Nitrilotriacetic acid	wastewater	$2\,\mu g\,L^{-1}$	DPP complexed to bismuth(III)	66
	natural, wastewater		single-sweep polarography of the Bi(III)–NTA[a] complex	67
Aromatic hydrocarbons	tap water, motor oil	$5–50\,\mu g\,L^{-1}$	LC with reductive ED at a glassy carbon electrode	16
	ground, surface, river, rain, drinking water	$0.26–0.71\,\mu g\,L^{-1}$	HPLC with amperometric detection at a glassy carbon electrode	17

[a] NTA, nitrilotriacetic acid.
DPP, differential pulse polarography.

A correct determination of nitrilotriacetic acid in the presence of Fe(III) and Al(III) has been described,[66] and applications to natural and wastewaters have been carried out.[67] Tables 3 and 4 show applications of EC methods to the analysis of hydrazines, hydroxylamine, and nitrilotriacetic acid.

5.4 Aromatic Hydrocarbons

Polycyclic aromaric hydrocarbons (PAHs) are products of an incomplete combustion of organic materials, and can be found in some environmental matrices. Table 4 shows applications of ED methods to the analysis of aromatic hydrocarbons in environmental samples.

Either LC or HPLC is used for the analysis of PAHs; the analysis can be carried out by previous oxidation of the analytes with Ce(IV), and the final product (quinones) detected by reductive LC/ED at -0.4 V. The procedure is applied to tap water and motor oil.[16]

The direct analysis of PAHs is carried out by oxidative HPLC/ED at $+1.35$ V. An SPE procedure is used for the preceding extraction/preconcentration step.[17]

5.5 Polychlorinated Biphenyls

PCBs have been produced in many countries under different trade names, e.g. Aroclor®, Delor®, Sovtol®, or Kanerol®. The best known is Aroclor®, which is a mixture of chlorinated biphenyls characterized and numbered by the total percentage of chlorine in the mixture. The PCBs are toxic, the lethal oral dose (LD_{50}) is $2–10\,g\,kg^{-1}$ in mammals, and produce cancer. Because of their toxicity, the use of PCBs has been subject to some governmental regulations in many countries.

The determination of PCBs is of great environmental concern, because their release from industrial processes, combined with their insolubility in water and their resistence to biological degradation, has resulted in widespread contamination of water and soil. For several years PCBs have been recognized as ubiquitous environmental pollutants and these molecules are still presents in the environment, even though the production of PCBs has been banned. The conventional methods for quantifying PCBs are GC/MS or GC with electron capture detection.[68] Table 5 shows applications of EC methods to the analysis of PCBs in environmental samples. Aromatic halogen-containing organic compounds can be reduced according to:[69]

$$RX + 2e^- + H^+ = RH + X^-$$

with reduction potentials being markedly affected by the nature and number of substituents in the aromatic ring. Although EC methods have not been widely applied for quantifying PCBs, some examples can be found, such as the following (all cited in[69]): Kemula and Kreminska (1960) combined column chromatography and polarography to separate various isomers of dichlorodiphenyltrichloroethane (DDT) quantitatively; Colas et al. (1964) used silica gel to separate a mixture of two isomers of endosulfan, followed by polarography in a water–acetone mixture; Supin and Budnikov (1973) used the properties of α-benzene hexachloride at a slow DME to its determination at levels down to $60\,\mu g\,L^{-1}$ in pure solution; and Farwell et al. (1975) reported the use of interrupted-sweep voltammetric analysis to identify polychlorinated insecticides and other polychlorinated aromatics. However, this method requires at least $9\,\mu g$ of relatively pure compound to obtain positive identification. Therefore it is not very helpful for the analysis of pesticide residues in the environment.

In 1984 Lam and Kopanica[18] carried out an important EC application for the environmental analysis of PCBs. They determined TCB by adsorptive stripping voltammetry at a HMDE in the concentration range $0.004–1\,mg\,L^{-1}$. Preconcentration is achieved by adsorption at a potential of -0.40 V, and desorption at -1.10 V. This method was applied to the analysis of waste and natural waters with a relative standard deviation (RSD)

Table 5 Environmental analysis of PCBs and phenols by EC methods

Analyte	Sample	Detection limit	Comments about the method	Ref.
PCBs	waste mineral oils	12 mg g^{-1}	dechlorination by sodium and potentiometric measurement	70
(TCB)	waste and natural water	0.0015 mg L^{-1}	adsorptive stripping voltammetry at a HMDE: deposition potential −0.4 V, potential range from −0.4 to 1.3 V	18
(Aroclors®)	industrial effluent water	0.39–3.3 µg L^{-1}	EC immunosensor, specific binding between PCB and anti-PCB antibody-immobilized conducting polymer matrix	19
Phenols (2-Nitrophenol)	seawater	0.03 mg L^{-1}	FIA coupled to differential pulse voltammetry at a bentonite-modified carbon paste electrode	88
(2-Methyl-4,6-dinitrophenol)	seawater	3.2 µg L^{-1}	differential pulse voltammetry at a hidepower-modified carbon paste electrode	86
(Total phenols)	industrial wastewater		LC or FIA system with two carbon electrode in series: coulometric and amperometric detectors	24
Phenols	surface water		peroxidase modified carbon paste/solid graphite electrode at −0.05 V (versus saturated calomd electrode)	93
	seawater	0.01–1.9 µg L^{-1}	LC with ED using a dual electrode analytical cell equipped with a coulometric detector and an amperometric electrode	20
	seawater	[a]0.9–6.1 µg L^{-1} [b]5–45 ng L^{-1}	LC with ED at a glassy carbon electrode at 1.25 V	21
	river, tap water	0.01–1 µg L^{-1}	LC with ED at a glassy carbon electrode at 1.1 V	22
	tap, wastewater	5×10^{-8} M	adsorptive stripping voltammetry at 1.8 V using a carbon paste electrode with solid paraffin as a binder	95
	industrial wastewater		amperometric biosensor based on polyphenol oxidase	101
	wastewater	0.01–0.12 mg L^{-1}	Capillary electrophoresis with ED	97
	municipal waste		HPLC with ED	98
(Catecol, phenol)	surface water	0.25 µg L^{-1}	tyrosinase-modified solid graphite electrode	92
		4 µg L^{-1}	tyrosinase containing apoxy/graphite electrode	92
	wastewater	2–3 nM	tyrosinase-modified solid graphite electrode	25
	river, wastewater		Biosensor: catecol is determined by the reduction of its oxidation product on glassy carbon electrode after conversion to quinone in an on-line coconut-based reactor by FIA	99
	river water	6 nM	dual enzyme electrode chromatographic detection; carbon paste tyrosinase amperometric detector using short-chain hydrocarbons as pasting liquids	100
(Priority phenolic pollutants)	effluent water	0.03–2 µg L^{-1}	LC with ED at a glassy carbon electrode	89
	tap, drinking water	<35 ng L^{-1}	HPLC with amperometric detection	96
	river water	>0.4 ng L^{-1}	HPLC with coulometric detection using a dual electrode analytical cell equipped with two glassy carbon electrodes	23
(Chlorinated phenols)	natural water	25 ng L^{-1}	HPLC with ED using a supported liquid membrane extraction system	102
(Phenol, *p*-cresol)	river, groundwater		tyrosinase modified carbon paste electrode coupled to a 50 ft shielded cable for field monitoring	94
(Phenol, *o*-cresol)	tap, wastewater		LC with amperometric detection at a glassy carbon electrode	26
(Phenol, alkyl-, hydroxy-, and chlorophenols)	waste, river water	2.75–950 µg L^{-1}	HPLC with EC dual detector	90

[b] After SPE.

of below 5%. The cyclic voltammogram of TCB yielded a sharp cathodic peak, about four times higher than the anodic peak. TCB was accumulated on the surface of the HMDE in the more positive potential range and later it was stripped off at more negative potentials.

The current measured in the voltammetric determination of TCB depends on the pH of the supporting electrolite. The optimun pH is in the range 6–7, where the TCB peak is well separated from hydrogen evolution. Because of the insolubility of TCB in water, voltammetric determination must be done in a buffer solution containing methanol. The dependence of the peak current on the TCB concentration was linear in the range 1×10^{-8}–1×10^{-6} mol L^{-1} TCB and the detection limit was found to be 1.5 μg L^{-1}.

Polarographically active metal ions such as Cu^{2+}, Pb^{2+}, Cd^{2+}, or Zn^{2+} would not interfere if their concentration in the sample solution was up to 10 time greater than that of TCB; otherwise, masking with EDTA was necessary. However, surface-active compounds and organic compounds exhibiting adsorption properties similar to those of TCB may interfere; so, DDT can be determined under practically the same conditions as TCB. Thus it interferes with the TCB determination. The procedure was applied to different kinds of water and the results agreed very well with those obtained by the spectrophotometric measurements (Table 6).

The screening of PCBs in used mineral oils is carried out by a fully automated robotic method based on the dechlorination by sodium and a potentiometric measurement. The robot performs the weigh-in of the sample, adds the reagents, develops an LLE and obtains the concentration using a chloride-selective electrode. The detection limit is below the regulatory limit established for a contaminated waste oil.[70]

A current trend dealing with the EC analysis of PCBs is the development of EC immunosensors.[47] Del Carlo and Mascini[71] have developed an EIA with amperometric flow-injection analysis. To do that, they used a horseradish peroxidase (HRP) as a label, and its application to the determination of PCBs. They employed a competitive assay, where conjugated PCB–protein (gelatin) was immobilized to the solid phase (microtitre assay plate) and the competition was carried out with PCB standard using a limiting amount of anti-PCB IgG. The extent of the competition was evaluated using a secondary, HRP labeled, IgG. The PCB range was 0.1–50 μg mL^{-1}. Another development is a disposable screen-printed electrode for the immunochemical detection of PCBs.[72] Three different EC approaches were compared (amperometry, chronoamperometry and differential pulse voltammetry) for the detection of α-naphthol and a DPP procedure was optimized to evaluate the detection of low levels of alkaline phosphatase, an enzyme which catalyzes the hydrolysis of α-naphthyl phosphate to α-naphthol. Finally, a competitive EIA for PCBs, made of alkaline phosphatase, was performed using the optimized ED of α-naphthol. The procedure was not applied to real water samples.

Sadik and Bender[19] have developed a direct EC immunosensor for the determination of PCBs in water. The assay is based on the measurement of the current due to the specific binding between PCB and anti-PCB antibody-immobilized conducting polymer matrix. The immunosensor showed a high selectivity for PCBs in the presence of a potential interference such as chlorinated anisole, benzenes, and phenols. Electrode antibody membranes were prepared using three main formats (Figure 2).

- *EC microassembly*. The PCB immunosensors were prepared by constant potential (0.7 V) EC deposition from a 0.2 M pyrrole monomer solution onto platinum or silver substrates. An antibody raised against PCBs served as the counterion in the polymerization process. Antibody layers were further adsorbed onto the pyrrol layer by dipping the polypyrrole (PPY)/$H_2PO_4^-$ electrodes into a solution containing PCB antisera, which was made up in phosphate buffer saline (PBS) buffer (pH 7.4).
- *Physical entrappment*. EC polymerization of the PPY/antibody membrane was carried out. The films were grown using a charge of 160 mC, and the thickness of the antibody layers was controlled by means of the charge which passed during the polymerization.
- *Passive adsorption*. A silver or platinum substrate (0.3 cm^2) was preconditioned and used as the base electrode. The antibody layers were also adsorbed onto the substrates by dipping the electrodes into a solution containing PCB antisera, which was made up in PBS buffer (pH 7.4). The electrodes were inmersed

in PBS at pH 7.4 after preparation for removal the adsorbed proteins and then thoroughly rinsed with PBS at pH 7.4, followed by air-drying. The dried PPY/antibody electrodes were stored covered at 4 °C.

Antibody membrane electrodes are characterized by using cyclic voltammetry, chronoamperometry, and enzyme-linked immunosorbent assay (ELISA) protocols. The immunoreaction detection technique employed is referred to as a pulse-accelerated immunoassay technique (PAIT). The analytical signal was generated by applying a pulsed waveform between +0.60 and −0.60 V with a pulse frequency of 120 and 480 ms. The oscillating potential reversibly drove the antigen-antibody binding process. The current arising from this process was monitored in real time.

The sensor can be used for analyte detection in a static or flow injection (FI) mode by applying pulsed potentials between the sensor surface (or WE) and the reference electrode. The current obtained can be directly related to the rate of EC reactions occurring at the working (or sensing) electrode, which may be related partly to the concentration of the analyte in solution. Linear calibration curves of the peak heights (nA) versus concentration ($\mu g\,L^{-1}$) were obtained for various Aroclors®. The immunosensor exhibited a high selectivity for PCBs in the presence of potential interferences such as the chlorinated anisole, the benzenes, and the phenols. The highest cross-reactivity measured for chlorinated phenolic compounds relative to Aroclor® 1248 was less than 3%. Recoveries of spiked Aroclors® 1242 and 1254 from industrial effluent water, rolling mill, and seafood plant pretreated water ranged from 103 to 106%. The detection method may be applied to the continuous monitoring of effluent such as waste streams and groundwater.

5.6 Phenols

Phenolic compounds are released into the environment in a variety of ways, because they are used in many industrial processes. These include the manufacture of industrial products, such as plastics, pharmaceuticals, dyes and pesticides; agriculture also uses insecticides containing toxic nitrophenols.[73–76]

The environmental concern of phenol pollution results from the high toxicity of many phenol derivatives to living organisms.[77] Many phenols have a well established reputation as toxic pollutants due to their toxicity and persistency in the environment. According to European Community legislation, the maximum admissible concentration of phenols in water for human consumption is $0.5\,\mu g\,L^{-1}$ for the total content and $0.1\,\mu g\,L^{-1}$ for individual compounds, excluding those natural phenols which do not react with chlorine; in bathing water the maximum admissible value is $5\,\mu g\,L^{-1}$.[78,79] The analysis of phenols is very important in environmental programs due to their presence in natural and wastewaters. The USEPA lists eleven phenols as priority pollutants.[80]

Different methods have been developed for the analysis of phenols. Traditional methods recommended for their determination are based on the measurement of an index of phenols using spectrophotometric methods based on 4-aminoantipyrine (4-AAP) or 2-nitrophenol;[81,82] the result is expressed as total phenols, as individual phenols are not measured. These procedures have also been adapted to FIA, involving in-line concentration by solvent and sorbent extraction.[73]

GC allows the speciation of the various substituted phenols after LLE. The USEPA Method 604 for phenols determination involves the serial extraction of an acidified sample with dichloromethane.[83] The extract is dried and exchanged to 2-propanol, typically using Kuderna–Danish glassware, after that the phenols are analyzed by GC using a flame-ionisation detector. Alternatively, USEPA Method 625 for extractable base/neutrals and acids can be used for phenols determination.[84] The major limitation of these GC methods is the extraction procedure, where losses can occur during the steps of extraction, concentration, and solvent exchange. The extraction is also very laborious and intensive, so it requires specialized glassware as well as the use of chlorinated solvents. Table 5 shows applications of EC

methods to the analysis of phenols in environmental samples.

EC methods have been applied to the determination of phenols, with or without a separation step. Differential pulse voltammetry[85,86] and FI differential pulse voltammetry[87,88] were used for the determination of several nitrophenols in spiked seawater and/or spiked river water employing modified carbon paste electrodes. The reduction waves of nitrophenols were used for quantification. Furthermore the interferent effects of several anionic species, cationic species, and other phenols were studied. The major interferences on individual nitrophenols were caused by some cationic species and other nitrophenols; chlorophenols, generally, did not interfere. The use of an adequate potential to accumulate certain nitrophenols on the WE can be used to avoid the effect of some interferents.[86] The modified carbon paste electrodes can be also used for oxidations and the determination of several phenols in real water samples. However its sensitivity and selectivity could be improved if a preconcentration and/or separation step is applied.

A FI method using a dual EC detector was described for the analysis of total phenols in water and wastewater samples.[24] The method relies on an in-line oxidative EC removal or an elimination of interferences at an upstream large surface area (coulometric) electrode combined with the oxidative detection of all phenols at an amperometric electrode. The method was compared with the standard colorimetric procedure based on 4-AAP. The results clearly indicate the increased accuracy of the FI method for the analysis of phenols in comparison with the data derived from the colorimetric procedure.
